Abstract

The Island Gold deposit is a high-grade orogenic gold deposit located in the Goudreau Lake Deformation Zone (GLDZ), within the Michipicoten greenstone belt. This belt is situated within the larger Wawa-Abitibi terrane which is an area of significant gold endowment in the Superior Province. This underground mine is operated by Alamos Gold Inc. (formerly operated by Richmont Mines Inc.). At the end of 2016, the Island Gold Mine had estimated indicated and measured resources of 478,800 tonnes at 5.94 g/t Au (91,400 oz) as well as inferred resources estimated at 3,041,800 tonnes at 10.18 g/t Au (995,700 oz). Simultaneously, proven and probable mineral reserves were estimated at 2,551,000 tonnes at 9.17 g/t Au (752,200 oz). This thesis integrates petrology, geochemistry, electron probe microanalysis, U-Pb zircon geochronology, and multiple sulphur isotopic study to characterize the nature and timing of alteration associated with the auriferous zones at this deposit.

The protoliths of pre-gold mineralization lithologies identified at the Island Gold deposit, listed from oldest to youngest, include dacitic volcanic rocks, iron formation, gabbro, and tonalite–trondhjemite. V_{GD} extensional and V_1-V_2 shear-related quartz (± carbonate) veins, that often contain visible gold, post-date and alter these lithologies. Protoliths of post-mineralization gold lithologies include quartz diorite, gabbro/low-K lamprophyre (spessartite), and silica-poor diorite–monzodiorite. Late V_3 extensional quartz-carbonate veins result in local, inconsistent alteration and remobilization of certain elements. Later tourmaline ribbons invade pre-existing structures. Lastly, diabase–quartz diabase dykes sharply cut all lithologies and vein types. Greenschist facies metamorphism has variably affected all lithologies, resulting in metamorphic minerals that mainly include actinolite, carbonates (mainly calcite), chlorite (ripidolite), chloritoid, epidote, hematite, plagioclase, quartz, and white mica.

Archean U-Pb LA-ICP-MS ages of 2735 ± 8 Ma and 2738 ± 9 Ma obtained from zircons in altered and least-altered dacitic samples are consistent with previous geochronological studies. Analysis of uniform cathodoluminescent zircons and rims in the altered sample yielded anomalous Proterozoic ages ranging from *c.* 975 to 1499 Ma, which are attributed to unidentified alteration event(s) that post-date auriferous quartz veining.

Alteration related to auriferous quartz veining at this deposit results in the significant and consistent enrichment of Au, K_2O, Rb, S, and Te as well as typically the depletion of Na_2O in alteration envelopes hosted by dacite, gabbro, and the tonalite–trondhjemite. Alteration minerals associated with V_1-V_2 auriferous quartz veining include biotite, Ca-Mg-Fe carbonates, chlorite (ripidolite), plagioclase, quartz, sulphides (pyrite ± pyrrhotite ± chalcopyrite), and white mica (muscovite ± phengite). The alteration associated with V_1-V_2 veining remains relatively consistent with varying distance parallel to the GLDZ and elevation.

Aside from auriferous alteration resulting in Na_2O depletion, alteration-derived biotite, and insignificant proportions of alteration-derived potassium feldspar at the Island Gold deposit, the gold-related alteration at orogenic gold deposits east of the Kapuskasing Structural Zone is similar to the alteration identified at the Island Gold deposit. This overall consistency of the alteration between these deposits and the Island Gold deposit supports a common genetic process for these orogenic gold deposits.

Multiple sulphur isotope study of sulphide minerals from auriferous quartz veins and associated ore zones dominantly suggests a mantle/igneous parentage. The auriferous fluid that produced these veins was likely derived from the mantle, exsolved from a cooling crustal intrusive body, or the dehydration of igneous rocks due to metamorphism.

Acknowledgements

As I write this section, I have come to realize and sincerely appreciate the considerable number of people that were involved with this project. I thank all of those involved because without their contributions, this thesis would not have been possible. Above all, this thesis has taught me that teamwork is needed to achieve any goal.

Co-supervisors Dr. Chris Yakymchuk and Dr. Shoufa Lin (University of Waterloo) provided guidance, managed project funding, helped with the interpretation of data, and proofread this thesis. I was fortunate to have them both as thesis supervisors. Regardless of their busy schedules, they always made time to answer my questions and were open to discussion. Dr. Chris Yakymchuk also assisted with LA-ICP-MS analyses and completed the reduction of the raw LA-ICP-MS data. Dr. Jean Richardson, Dr. Brian Kendall (University of Waterloo), and Dr. Patrick Mercier-Langevin (Natural Resources Canada), proofread this thesis and provided guidance and recommendations. I learned so much as a result of everyone's input and thank them for their guidance, patience, and hard-work.

I want to thank Katia Jellicoe, Ivan Edgeworth, Adrian Rehm, Carson Kinney (past and present students at the University of Waterloo), and the Geology team and other staff at the Island Gold mine for their support including their assistance with work in the field, at the mine, and/or in the lab. Without their help, ideas, and expertise, this thesis would not have come to fruition. I hope that this thesis provides answers to some of the questions that were brought forward over the course of this project.

Valérie Bécu (Natural Resources Canada) created purchase orders and managed the shipment of samples to Activation Laboratories Ltd. and Vancouver Petrographics Ltd. She also managed the funding allocated by Natural Resources Canada/the Geological Survey of Canada for analyses. In addition, she provided the STPL geochemical reference materials as well as compiled and provided the results of previous analyses of these reference materials. Kathleen Lauzière (Natural Resources Canada) managed the Targeted Geoscience Initiative Program and compiled sample information and whole-rock geochemistry data for the open file report and database. I want to express my gratitude to Valérie and Kathleen for their advice as well as invaluable efforts which ensured that this project ran smoothly.

Sulphur isotopic laboratory analyses were conducted by Dr. Nanping Wu and Dr. James Farquhar at the University of Maryland Stable Isotope Laboratory. They also read preliminary portions of this thesis pertaining to sulphur isotopes and provided suggestions and guidance regarding the interpretation of this data. Additional sulphur isotopic analyses were conducted by Rick Heemskerk and staff at the University of Waterloo-Environmental Isotope Laboratory. SEM-MLA laboratory work was conducted by Dr. David Grant, Dylan Goudie, and Memorial University staff at the CREAIT Network's Micro Analysis Facility SEM/MLA Lab (at the Bruneau Centre). Electron microprobe laboratory analyses were conducted with the help of Marc Beauchamp at the Electron Microprobe Laboratory which is part of the Earth and Planetary Material Analysis Laboratory at Western University. Gold coating and cathodoluminescence imaging of zircons were conducted by Dr. Nina Heinig at the Waterloo Advanced Technology Laboratory. Dr. Shuhuan Li taught me how to operate the SEM-EDS at the Environmental Particle Analysis Laboratory (University of Waterloo) and allowed me to use it for analysis of samples for this thesis. Whole-rock geochemical laboratory analyses were conducted by staff at Activation Laboratories Ltd. (Actlabs) in Ancaster, Ontario. Thin sections were created by staff

at Vancouver Petrographics Ltd. in Langley, British Columbia. I wish to express my sincere gratitude to all those involved with the work and support summarized in this paragraph.

Thanks to those that provided funding for this thesis including Alamos Gold Inc., Richmont Mines Inc. (acquired by Alamos Gold Inc. in 2017), the Geological Survey of Canada/Natural Resources Canada (Targeted Geoscience Initiative), the Natural Sciences and Engineering Research Council, and the University of Waterloo. A variety of other support, such as accommodations and meals, were also provided by Alamos Gold Inc./Richmont Mines Inc. and associated staff while conducting field work.

Lastly, I want to thank Sonja Mazurak-Ciufo, Holden Ciufo, David Ciufo, and Christine Henstridge for their assistance with grammatical proofreading and their unwavering support. Without them I would not have found my passion for geology, and for that, I am eternally grateful. I must add that I am thoroughly impressed by their ability to patiently sit through my frequent, and typically unprompted, informational sessions about rocks.

1.0 Introduction

Orogenic gold deposits are the source of ~75% of the gold obtained throughout human history (Phillips, 2013). These economically important deposits are typically generated in mid-crustal rocks that have been subject to deformation and greenschist- to lower amphibolite-facies metamorphism. Gold is carried by hydrothermal fluids through orogeny-related, crustal-scale structures that act as conduits for these fluids (Groves, 1993; Goldfarb et al., 2001; Tomkins, 2013). Gold is deposited when changing chemical or mechanical conditions cause the gold-rich fluids to no longer be in equilibrium with their surroundings (Tomkins, 2013). However, the source and chemistry of these gold-bearing fluids, the chemical complexes that carry the gold in the fluids, the changes in conditions that cause the gold to precipitate, and the tectonic environments associated with such deposits are genetic aspects that are commonly unclear (Tomkins, 2013). A variety of genetic models have been proposed, many of which could be reasonable approximations for specific deposits but cannot be universally applied. As a result, detailed studies of individual orogenic gold deposits is crucial for developing genetic models that can be applied locally and regionally.

Greenstone belts within the Superior Province of the Canadian Shield host many world-class orogenic gold deposits and these deposits are significant economic drivers for many communities (Goldfarb et al., 2001). This study focuses on the Island Gold deposit located ~35 km north of Wawa, Ontario, and a 30-minute drive from the town of Dubreuilville (Figure 3). This deposit is situated ~100 km southeast of the Hemlo greenstone belt which contains the Hemlo gold deposit (Figure 2). The Island Gold mine is easily accessible by road and is owned and operated by Alamos Gold Inc. The Island Gold deposit has some of the highest-grade gold intersections in the Superior Province (Adam et al., 2017). It is located within the Goudreau Lake Deformation Zone (GLDZ) and this is thought to be the conduit that focused the fluids that resulted in gold mineralization. This deformation zone has been correlated with the large, gold-rich fault systems east of the Kapuskasing Structural Zone (Leclair et al., 1993). Some important areas of gold mineralization east of the Kapuskasing Structural Zone include the Kirkland Lake, Timmins, and Rouyn-Noranda mining camps (Figure 2). The Island Gold deposit therefore provides a unique opportunity to study orogenic ore-forming processes at an easily accessible, high-grade orogenic gold deposit at the less-studied western extent of this economically important fault zone.

This thesis integrates geochemistry, geochronology, petrography, scanning electron microscopy, and sulphur isotope analysis to identify the protoliths of altered lithologies, fully characterize the alteration associated with the auriferous hydrothermal fluids, provide effective indicators for gold mineralization, determine the age(s) of gold mineralization, and constrain the source of the auriferous fluid at the Island Gold deposit. This will assist with ore zone targeting, provide regional exploration vectors, update the genetic model and geological history of the deposit, and contribute to the understanding of orogenic gold deposits globally. A companion study has been conducted by Katia Jellicoe, a MSc student at the University of Waterloo, that focuses on the structural geology associated with the Island Gold deposit (Jellicoe, 2019).

The following thesis is divided into a total of seven sections. The remainder of the first section (1.1) provides the geological setting of the Island Gold deposit. The second section (2) outlines the research objectives of this thesis. Section 3 details the analytical methods used and Section 4 summarizes the results. Section 5 discusses the implications of the results and Section 6 presents the conclusions. Recomendations for future work are discussed in Section 7. All supplementary information is included in the Appendices.

1.1 Geological Setting

1.1.1 Superior Province

The Island Gold deposit is located within the Superior Province, which makes up a large portion of the Canadian Shield and extends from Quebec in the east to Manitoba in the west. The Superior Province is dominated by Mesoarchean to Neoarchean tonalitic-trondhjemitic-granodioritic (TTG) suites and also contains sublinear and anastomosing greenstone belts (Percival et al., 2012). These greenstone belts are composed of metavolcanic rocks as well as minor metasedimentary rocks (Percival et al., 2012). The Superior Province is divided into fault-bounded terranes that have been interpreted to represent north-directed terrane accretion between 2720 and 2680 Ma (Percival et al., 2012; Bédard and Harris, 2014). Archean rocks of the Superior Province are intruded by Proterozoic and Phanerozoic mafic dyke swarms.

The margins of the Superior Province are bounded by Proterozoic orogenic belts (Figure 1; Hoffman, 1988). Beginning at 1.9 Ga, the Paleoproterozoic Trans Hudson Orogen sutured the Hearne and Wyoming Provinces to the western and northern margins of the Superior Province (Berman et al., 2007). To the northeast, the New Quebec Orogen (2.17–1.77 Ga) welds the

southeastern part of the Rae Province to the Superior Province and the Torngat Orogen (~1.8 Ga) connects the Nain Province to the Superior Province (Machado et al., 1997; Van Kranendonk, 1996; Hoffman, 1988). To the south, the Superior Province is bounded by the 1.90–1.83 Ga Penokean Orogen as well as the younger 1.14 Ga Keweenawan rift (Hoffman, 1988). The Neoproterozoic Grenville Orogeny bounds the eastern margin of the Superior Province (Rivers et al., 2012). As a result of these orogens, in addition to those related to the amalgamation of the Superior Province itself, this province exhibits polyphase deformation. Large fault systems are concentrated in greenstone belts in the interior of the craton and are commonly associated with gold deposits (Percival et al., 2012) including the Island Gold deposit.

The mechanism for the amalgamation of the terranes that comprise the Superior Province is still debated (Bédard, 2006; Bédard, 2013; Wyman, 2013a; 2013b) and there are currently two dominant models. Subduction-driven accretion of terranes in the Archean Superior Province is proposed based on a uniformitarian model of plate tectonics that includes mid-ocean ridge spreading and subduction (Cawood et al., 2006, Warren, 2011, Wyman, 2013a). However, notable differences arise when examining Archean geology and comparing it to the Proterozoic and Phanerozoic Eons. These include the lack of high pressure-high temperature lithologies and adakites, presence of komatiites, and the dominance of TTG suites (Bédard, 2006). As a result, a second model that involves vertical or plume-driven tectonics was hypothesized for the Superior Province. This model uses mantle wind and plumes as the dominant forces that drove terranes northward to create the composite Superior Province (Bédard, 2006; Bédard and Harris, 2014). Others suggest that the Neoarchean was a transition period in the Superior Province where both subduction-driven and vertical tectonic processes were operating (Lin, 2005; Lin and Beakhouse, 2013). Due to this controversy, it is not clear whether one or parts of each of these models explains the history of the Superior Province.

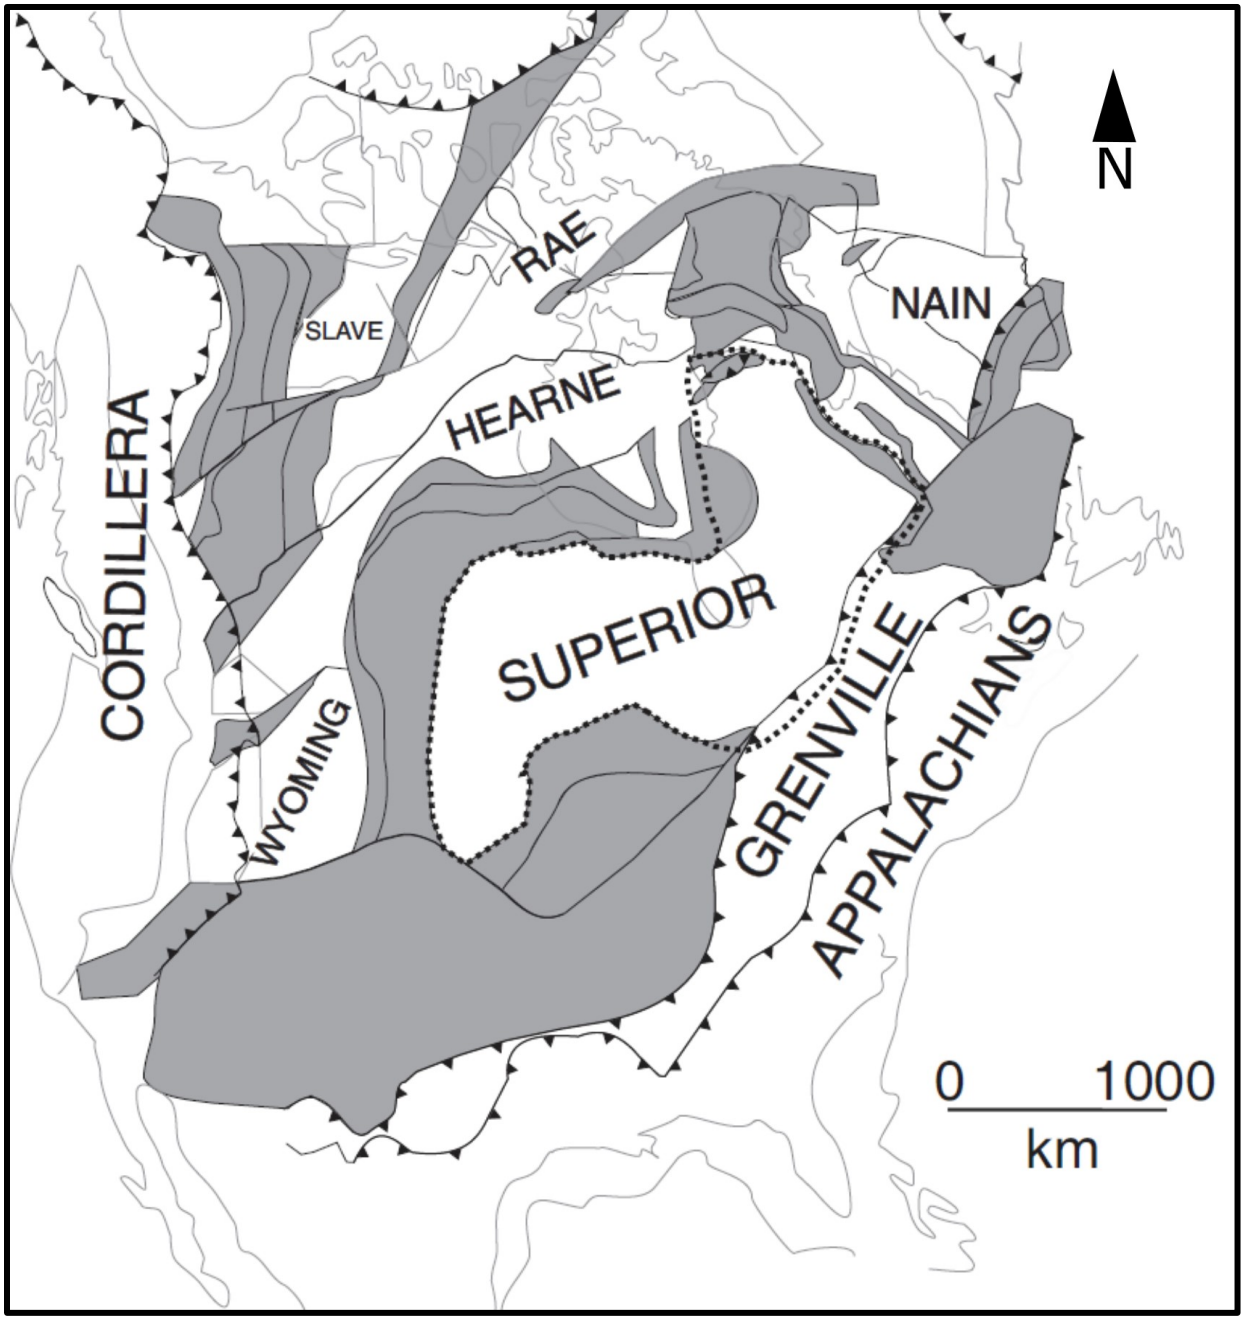

Figure 1. *Tectonic framework of the North American continent. Paleoproterozoic domains related to the formation of Laurentia are shown in grey (Percival et al., 2012). Modified from Percival et al. (2012); After Hoffman (1989).*

1.1.2 Wawa-Abitibi terrane

The Wawa-Abitibi terrane is one of the largest terranes in the Superior Province and is also a region of significant mineral wealth within the Superior Province (Figure 2). This terrane is composed of sublinear, east–west trending supracrustal belts enveloped by larger granitoid-dominated regions. Plutonic and volcanic rocks range in age from approximately 2.9 to 2.6 Ga and 2.9 to 2.7 Ga, respectively (Percival et al., 2012). In some cases, volcanic rocks are unconformably overlain by greywacke and conglomerate sedimentary rocks (Percival et al., 2012). Most authors agree that the Wawa and Abitibi terranes are broadly correlative (Percival and Easton, 2007) but earlier studies separated them into distinct subprovinces/terranes (Williams, 1989). The Kapuskasing uplift that exposes deeper gneissic crust (Percival et al., 2012) geographically separates the historical Wawa and Abitibi terranes. The Island Gold deposit is located within the Wawa-Abitibi terrane, west of this Kapuskasing Structural Zone (Figure 2).

Moving from the west towards east, the Wawa-Abitibi terrane is bounded to the north by the Western Wabigoon, Marmion and Opatica Terranes and to the south by the Minnesota River Valley Terrane, Pontiac Belt and Grenville Province (Percival et al., 2012). The Wawa-Abitibi terrane collided with the Winnipeg River-Marmion Terrane at 2690 Ma during the Shebandowanian Orogeny (Percival et al., 2012). This was followed by the collision with the Minnesota River Valley Terrane during the Minnesotan Orogeny which began at 2685 Ma (Percival et al., 2012). Geological histories at various localities within this terrane have been explained with reference to evolving oceanic environments including volcanic arcs, plateaus, accretionary margins and rifts (Thurston, 1994; Bédard and Ludden, 1997; Wyman and Kerrich, 2010).

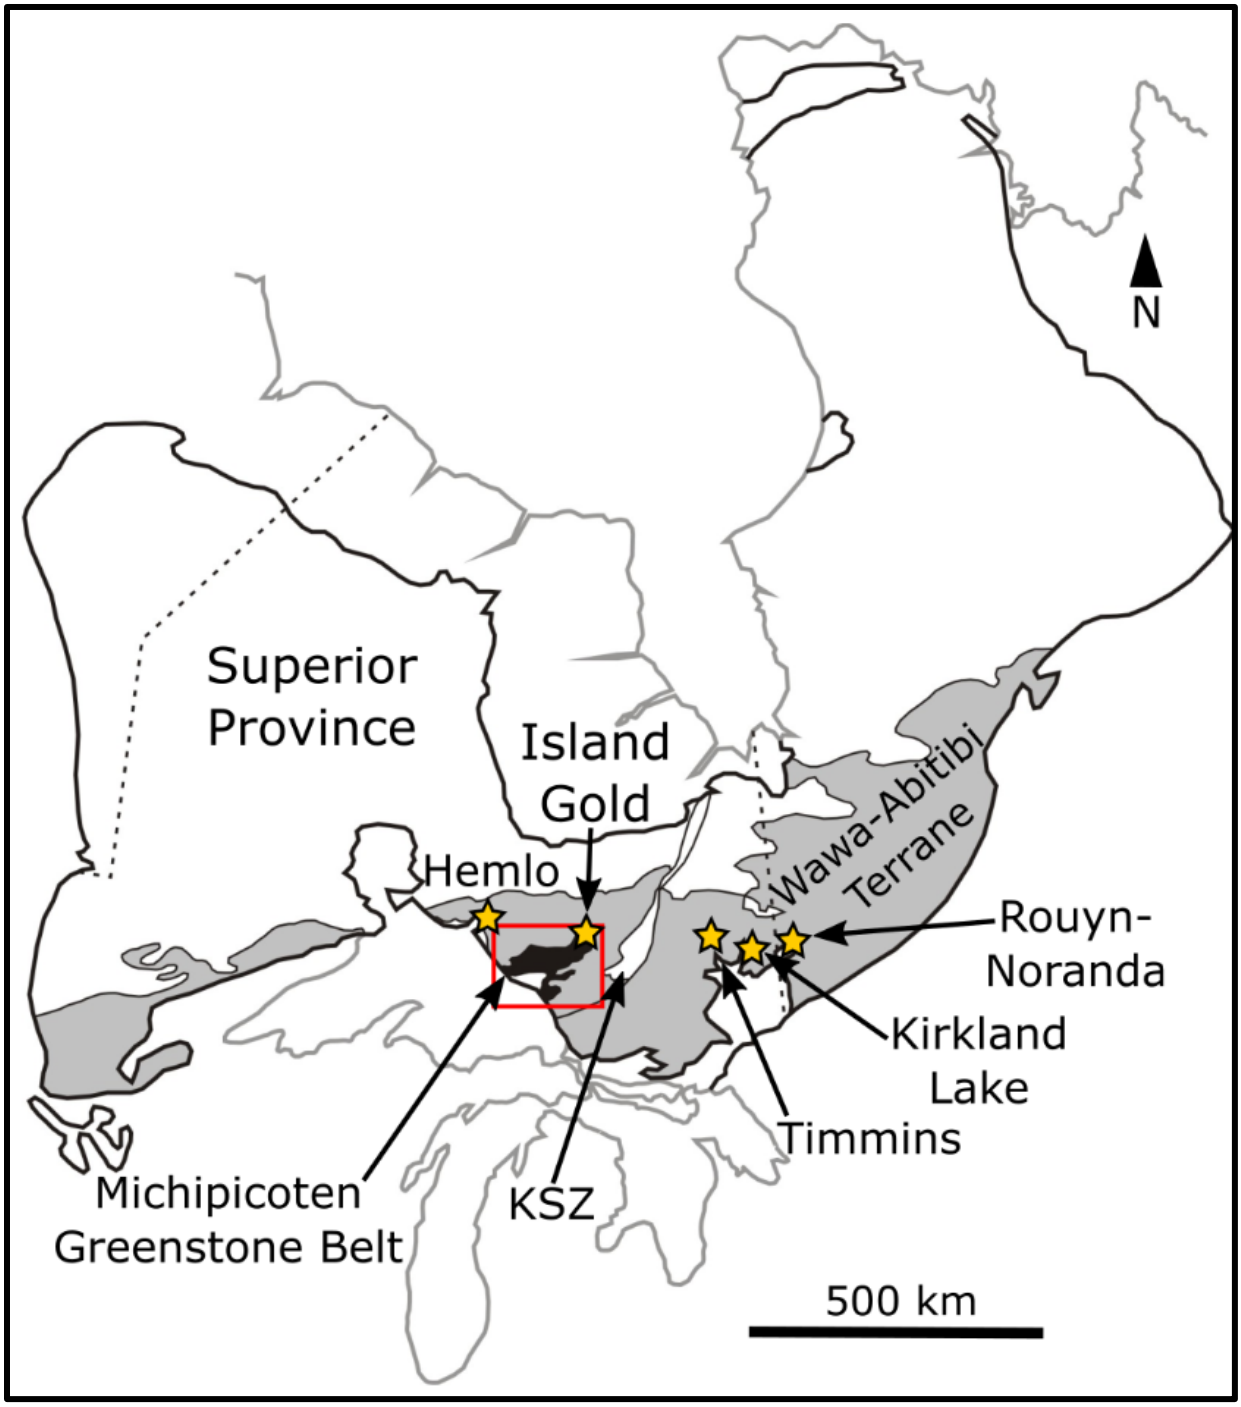

Figure 2. *Position of the Michipicoten greenstone belt within the Wawa-Abitibi terrane of the Superior Province. Location of a variety of large gold camps as well as the Island Gold deposit (gold stars). The red rectangle outlines the extent of Figure 3. KSZ=Kapuskasing Structural Zone. Modified from Card (1990), Williams et al. (1991), and Jellicoe (2019).*

1.1.3 Michipicoten greenstone belt

The Michipicoten greenstone belt is an approximately east-west trending belt within the Wawa Subprovince (Figure 2) and is dominantly composed of metamorphosed volcanic and sedimentary rocks as well as various intrusive rocks (Figure 3). The volcanic rocks are subdivided into three volcanic cycles of *c*. 2900, 2750 and 2700 Ma in age (Turek et al., 1984; 1992; Arias and Helmstaedt, 1990; Sage, 1994). The rocks of the first, second and third cycles of volcanism are part of the Hawk, Wawa and Catfish assemblages of Williams et al. (1991), respectively (Sage, 1994). These felsic–intermediate volcanic rocks are mineralogically and compositionally similar, making it challenging to distinguish which cycle they are from without geochronology (Sage, 1994). The bottom of each cycle is composed of ultramafic–mafic rocks and the sequence progressively becomes more felsic upwards through the cycle. Lower mafic and upper felsic portions of the cycles are often separated by discontinuities (Sage, 1994) but can be locally conformable (Sylvester et al., 1987). Ultramafic rocks in the 2900 Ma cycle consist of komatiites whereas mafic units in the younger cycles are tholeiitic basalts. The 2900 and 2750 Ma cycles are capped by an unconformity separating the volcanic rocks from overlying iron formations. These iron formations are interpreted to represent periods of relatively quiet sedimentation with hydrothermal input of iron from submarine vents in the sedimentary basin (Sage, 1994; Bekker et al., 2010). The supracrustal rocks are cut by dioritic–gabbroic intrusions as well as granitic stocks of various ages (Sage et al., 1996). This is likely a result of magmatism associated with each of the volcanic cycles.

The Doré metasedimentary rocks are extensive in the Michipicoten Greenstone Belt (Figure 3) and unconformably overlie the 2700 Ma cycle. Wacke and conglomerates with a wacke matrix comprise the majority of this unit. Clasts in the conglomerate consist of mainly felsic–intermediate volcanic rocks and granitic rocks (Sage, 1994). As discussed in Sage (1994), the clasts and matrix have U-Pb zircon ages that are equivalent to or slightly younger than the third cycle volcanic rocks (Turek et al., 1982; Turek et al., 1984; Corfu and Sage, 1987; Corfu and Sage, 1992; Turek et al., 1992). This suggests that the third cycle volcanic rocks and their intrusive equivalents are the source of the Doré metasedimentary rocks (Sage, 1994). Relatively undeformed diabase dykes of early Proterozoic age crosscut the deformed supracrustal rocks. The Michipicoten greenstone belt is bordered by granitoids that are mainly younger than rocks within the greenstone belt (Sage, 1994). Proximal to the margins of the greenstone belt, U-Pb

ages obtained from these external granitoids are younger than or of equivalent age to the 2750 Ma volcanic cycle (Turek et al., 1982). Approximately 25 km away from the eastern margin of the Michipicoten greenstone belt, 2920 Ma tonalitic gneisses are present (Moser et al., 1991). It is unclear how these distant older gneisses relate to the younger granitoids immediately surrounding the greenstone belt (Sage, 1994).

The Michipicoten greenstone belt reached amphibolite facies at its margins and only greenschist facies at the centre. This belt is interpreted to be an originally monoclinal sequence that was affected by both horizontal and vertical components of motion including thrusting, folding and shearing (Sage, 1994). It is unclear whether the higher metamorphic grade at the margins of the belt and the pervasive deformation are a result of subduction-related collision or vertical tectonic processes (Sage, 1994). Most studies published between 1970 and 1995 have interpreted the tectonic environment to involve an island arc transitioning into a continental arc (Sylvester et al., 1987; McGill, 1992; Sage, 1994). Both north-dipping (Williams, 1989) and south-dipping (Sage, 1994) subduction zones have also been hypothesized. More recently, vertical tectonics involving sagduction of the denser supracrustal rocks and diapirism of younger tonalites on either side have also been suggested (Lin and Beakhouse, 2013).

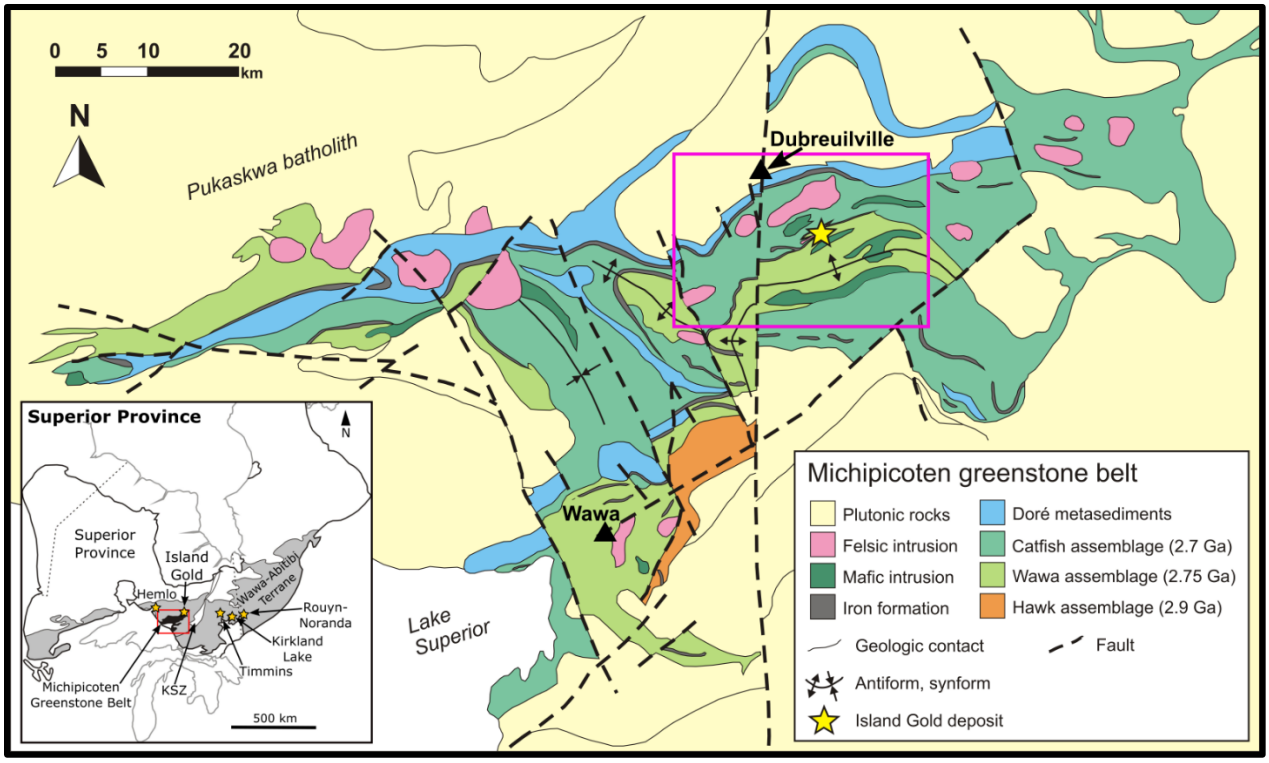

Figure 3. *Geological map of the Michipicoten greenstone belt. Modified from Heather and Arias (1987), Williams et al. (1991), and Jellicoe (2019). The purple rectangle outlines the extent of Figure 4. Inset shows the location of the Michipicoten greenstone belt within the Superior Province map (modified from Card, 1990; Williams et al., 1991; Jellicoe, 2019).*

1.1.4 Local geology of the Island Gold deposit area

The Island Gold deposit is located within the Goudreau-Lochalsh gold district which is part of the Wawa gold camp. There are several closed gold mines and many gold showings located in or associated with the Goudreau Lake Deformation Zone (GLDZ) which is approximately 4.5 km wide and over 25 km in length (Heather and Arias, 1987; Figure 4). This deformation zone records sinistral deformation and, based on the association of gold deposits and showings with this deformation zone, it is thought to be the conduit that provided auriferous fluids to the district (Turcotte and Pelletier, 2008; Adam et al., 2017; Jellicoe, 2019). The GLDZ and the Island Gold deposit are located on the northern limb of a regional anticline in the northern portion of the Michipicoten greenstone belt (Figure 4). Rocks within the GLDZ have been metamorphosed to greenschist facies and were subject to various degrees of shearing and hydrothermal alteration (Heather and Arias, 1987).

The Island Gold deposit is hosted within felsic–intermediate volcanic rocks that were generated during the second cycle of volcanism (Arias and Helmstaedt, 1990). These volcanic rocks include tuffs, flows, intrusive rocks, and pyroclastic fragmental rocks (Adam et al., 2017). These second cycle volcanic rocks are capped to the north by the Goudreau Iron Range which separates the second cycle volcanic rocks from the third cycle volcanic rocks. All volcanic units in this area generally strike 070–090° and have subvertical dips (Adam et al., 2017).

Within the GLDZ, the trondhjemitic Webb Lake stock hosts the Magino deposit (Figure 4). Similar to the volcanic units, the Webb Lake stock strikes ENE (Figure 4) and dips steeply to the north (Figure 5). Other large intrusive bodies nearby include the Herman Lake nepheline-syenite intrusive complex and the Maskinonge Lake granodiorite stock (Figure 4). Various other smaller intrusive units of various ages have been identified at the Island Gold deposit but, in many cases, their protoliths are obscured due to metamorphism, deformation and alteration. Detailed geochemical and petrographic study has not yet been performed on many of these lithologies. Northerly-striking, undeformed diabase intrusions are also present.

Three distinct deformation events were identified in Jellicoe (2019) and are summarized below. The first regional compressional event (D1) developed the S1 cleavage and large F1 folds. North-side-up transpression (D2) resulted in the development of the S2 foliation and the GLDZ which are subparallel to each other. This deformation event was also synchronous with metamorphism and the emplacement of the gold-bearing quartz veins at the Island Gold deposit.

Dextral, south-side up transpression (D3) resulted in F3 folds and S3 cleavage which partially overprint and deform pre-existing structures (Jellicoe, 2019).

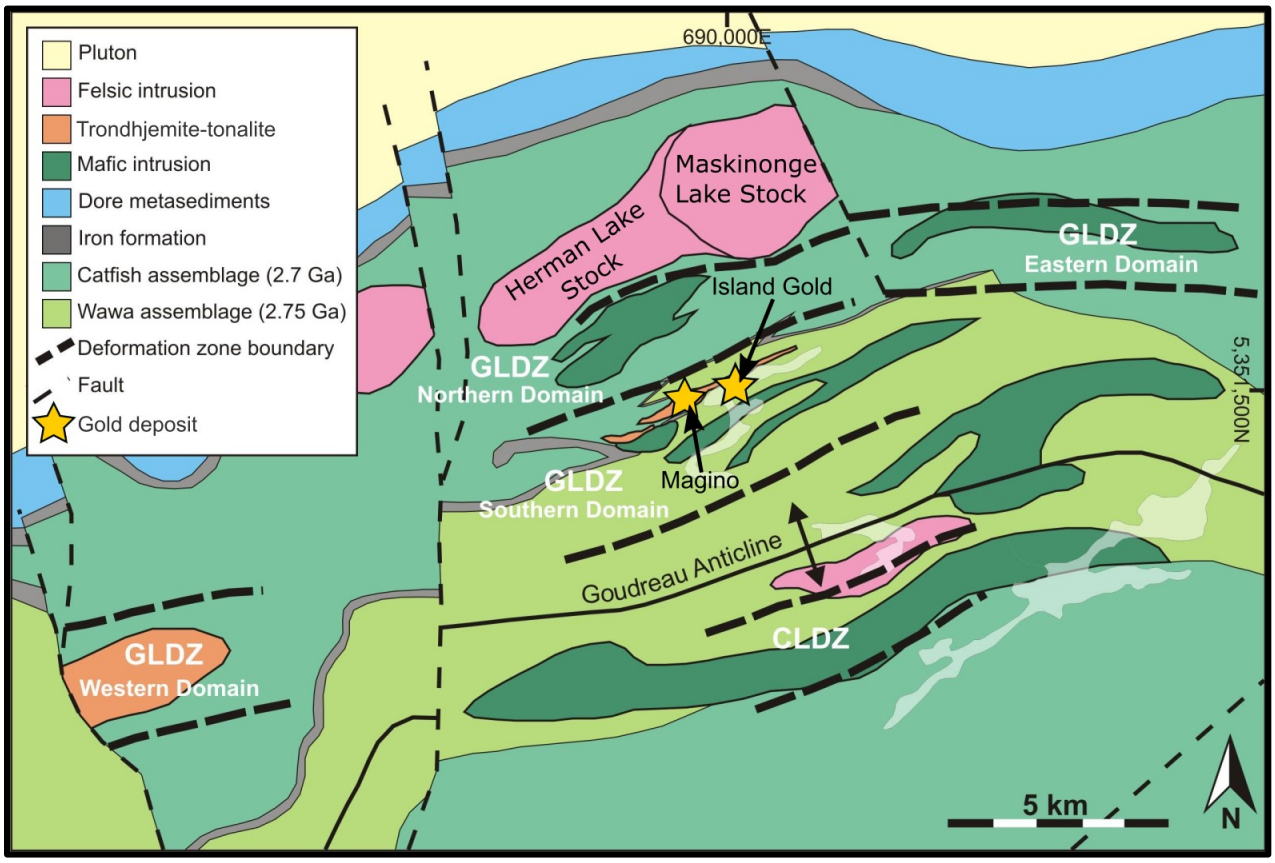

Figure 4. *Local geology map of the Island Gold deposit and surrounding area. Modified from Heather and Arias (1987), Williams et al. (1991), and Jellicoe (2019). GLDZ: Goudreau Lake Deformation Zone. CLDZ: Cradle Lake Deformation Zone.*

1.1.5 Gold mineralization and veining

At the Island Gold deposit, gold is concentrated within multiple, subparallel zones that have an east–northeast strike and a steep southerly dip (Figure 5). Between the 400 and 500 m levels, these major ore zones are inflected towards the south (Adam et al., 2017). These ore zones consist of two gold-bearing quartz (± carbonate) vein types (V_1 and V_2). V_1 veins are shear veins while V_2 veins are extensional veinlets. Both of these veins are believed to have formed during the same gold mineralization event, are intimately associated with each other, and cross-cut each other (Jellicoe, 2019). An envelope of hydrothermal alteration and high strain centres around V_1-V_2 veins and decreases in intensity moving outwards. It is difficult to differentiate the effects of a V_1 vein versus a V_2 vein on the surrounding wall rock due to their close association and as a result, the alteration associated with these veins is studied together in this thesis. The alteration that typically surrounds these gold-bearing quartz veins has been termed API (Alteration Package Island) by Alamos geologists. Mainly based on macroscopic study, API is thought to have been produced due to a combination of silicification, sericitization, feldspathization, carbonatization, sulphidization, chloritization, and biotitization (Adam et al., 2017). Prior to this thesis, the author is not aware of any petrographic and geochemical studies that focus primarily on the auriferous alteration at the Island Gold deposit. Alteration halos range up to 8 m in size (Adam et al., 2017) and the degree of alteration have been characterized using subjective terms ranging from very weak to very strong. A third vein type (V_3) is also present but these are gold-barren, quartz-carbonate extensional veins that cross-cut ore zones (Jellicoe, 2019). Tourmaline (± quartz ± carbonate) veins (V_4) post-date V_3 veins and invade/cross-cut all pre-existing structures and lithologies (Jellicoe, 2019). Unlike the gold-bearing quartz veins, V_3 and V_4 veins do not typically result in significant alteration of the surrounding wall rock.

Mine geologists have divided auriferous zones at the Island Gold deposit into two major areas of gold mineralization that are further subdivided: The Island Gold Zones (Main and Lower portions; Figure 5) and the Goudreau Zone. Other gold zones are also present on the property (Adam et al., 2017). The Goudreau Zone is unique from the Island Gold Zones because in addition to V_1-V_2 gold mineralization, this zone hosts a tightly-folded, gold-bearing, extensional quartz (± carbonate) vein (V_{GD} vein; Jellicoe, 2019). This vein set generally has a NNE-SSW strike and an average dip of 30° towards the east (Adam et al., 2017). Shears that host V_1-V_2 veins are observed offsetting V_{GD} veins (Jellicoe, 2019). For simplicity, quartz ± carbonate veins

are often referred to simply as veins or quartz veins in this thesis. VGD, V1, V2, V3, and V4 vein types at the Island Gold deposit were identified in Jellicoe (2019). Subscripts are applied to these vein identifiers in this thesis (V_{GD}, V_1, V_2, V_3, and V_4).

Hydrothermal alteration halos surround each of these vein types. The majority of the ore zones at this deposit (> 90%) are hosted by quartz veins within the felsic–intermediate volcanic rocks and a small amount (< 10%) are hosted by gabbro. Ore zones hosted by quartz veins in the Webb Lake stock are not common at the Island Gold deposit. However, this lithology is the main host lithology at the nearby Magino gold deposit (Turcotte and Pelletier, 2008) which is located to the west and along strike with the Goudreau Lake Deformation Zone.

Despite being hosted by different lithologies, gold mineralization within the Magino and Island Gold deposits are believed to have resulted from similar processes along the same major structures (Heather and Arias, 1992). Both of these deposits are classified as greenstone-hosted orogenic gold deposits (Adam et al., 2017; Turcotte and Pelletier, 2008). In the case of these two deposits, the structural conduit for auriferous fluids is believed to be the GLDZ. The Kremzar deposit is approximately one kilometre north of the GLDZ and is hosted within the third cycle mafic volcanic rocks and is controlled by a northwest-trending splay of the GLDZ (Adam et al., 2017).

At the end of 2016, the Island Gold Mine had estimated indicated and measured resources of 478,800 tonnes at 5.94 g/t Au (91,400 oz) as well as inferred resources estimated at 3,041,800 tonnes at 10.18 g/t Au (995,700 oz) (Adam et al., 2017). Simultaneously, proven and probable mineral reserves were estimated at 2,551,000 tonnes at 9.17 g/t Au (752,200 oz) (Adam et al., 2017).

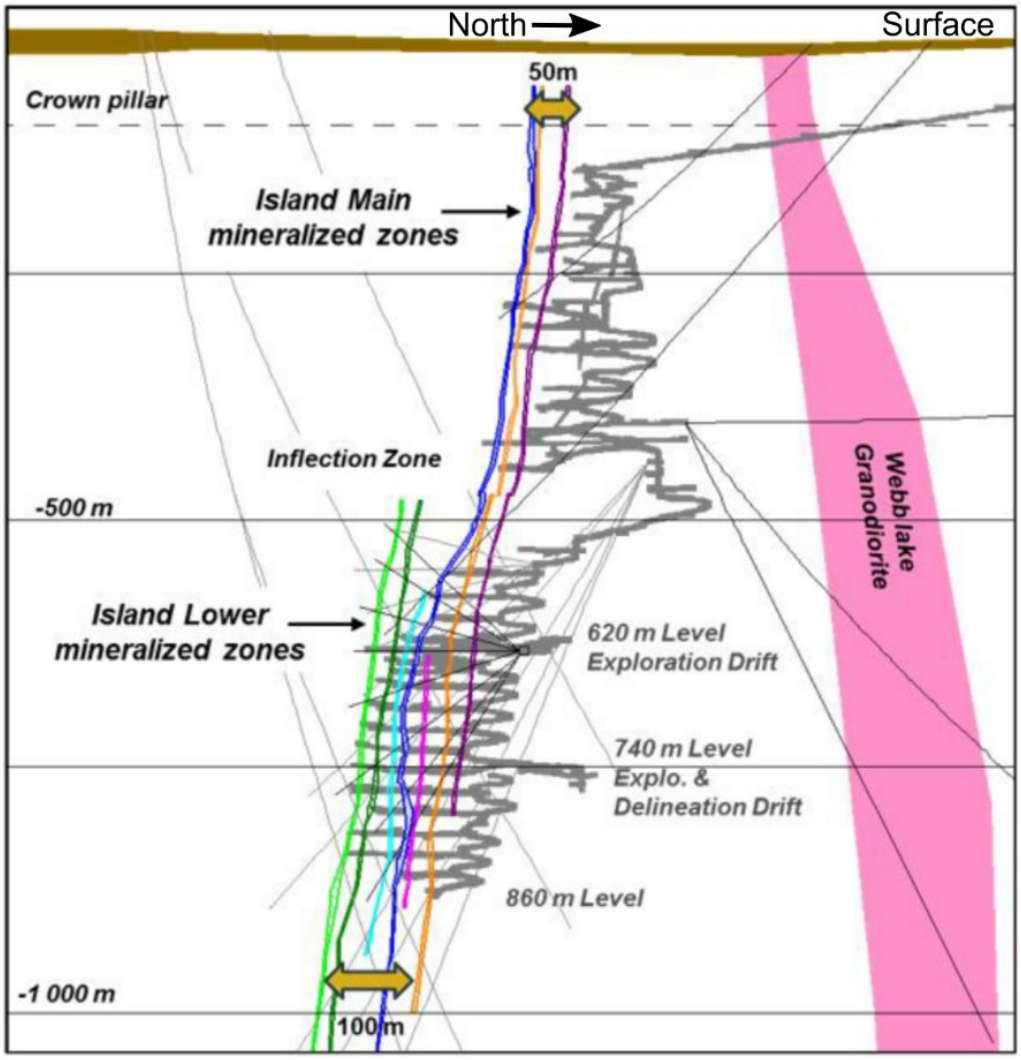

Figure 5. *Cross section displaying a portion of the Island Gold deposit. The location of some of the existing ramps and drifts, major ore zones, and the Webb Lake stock are displayed. Modified from Adam et al. (2017).*

2.0 Objectives, purpose, and applications

The five main objectives of this thesis focusing on the Island Gold deposit are:

1) Determine the protoliths of major lithologies and the effects of metamorphism on these lithologies;
2) Characterize the alteration envelopes associated with various gold-bearing quartz veins and compare them with alteration at other orogenic gold deposits east of the Kapuskasing Structural Zone;
3) Establish mineralogical indicators and geochemical vectors for gold mineralization;
4) Constrain the source of the gold-bearing fluid using multiple sulphur isotopes; and
5) Determine the age(s) of gold mineralization.

2.1 Protoliths and metamorphism

Due to the hydrothermal alteration associated with veining, deformation, and metamorphism it is often difficult to determine the protolith(s) of lithologies at the Island Gold deposit. However, identifying the protoliths of metamorphosed and altered lithologies is key to unravelling the full geological history, including the volcanic-sedimentary sequence, in order to target new deposits in the area. Through whole-rock geochemistry, petrography, scanning electron microscopy with energy dispersive spectroscopy (SEM-EDS), and electron microprobe analysis, this study identifies the protoliths or confirms previously identified protoliths of the various lithologies commonly encountered at the Island Gold deposit. This thesis also identifies the effects of metamorphism on these lithologies. Using mineral proportions and/or whole-rock geochemical data from least-altered samples of each lithology, an industry-standard geological name is assigned for each interpreted protolith.

2.2 Auriferous alteration

Characterization of the alteration envelopes associated with the auriferous quartz vein corridors is the major focus of this thesis. Prior to this study, the alteration envelopes at the Island Gold deposit were mainly studied by mine geologists macroscopically and through limited geochemistry. Defining the signature of these alteration envelopes is crucial because they are significantly larger than the ore zones themselves. As a result, they are easier exploration targets and, if intersected, can be used to converge on ore zones.

This thesis identifies alteration mineral assemblages and geochemical vectors towards mineralized zones for each of the main host lithologies at this deposit (dacitic volcanic rocks, gabbro, and the Webb Lake stock). This will assist with the identification of weak alteration and

thereby help locate ore zones. The alteration envelopes are subdivided into zones based on the intensity of alteration and this is quantified using geochemistry. This addresses the use of the subjective terms currently used for describing the alteration halo surrounding the ore zones at the Island Gold deposit (strongly, moderately, and weakly-altered) by providing quantitative underpinning for these terms. This will also improve the consistency of mapping alteration envelopes and assist with the correlation of ore zones.

The alteration identified at the Island Gold deposit is also compared to the alteration described in previous studies of major orogenic gold deposits in the Timmins, Kirkland Lake, and Rouyn-Noranda mining camps (Figure 2; Dinel et al., 2008; Moritz and Crocket, 1991; Kishida and Kerrich, 1987; Martin, 2012; Bigot, 2012; Couture and Pilote, 1993) and similarities and differences are discussed. Similar to the first objective of this thesis (Section 2.1), analytical techniques used to achieve this second objective include: Whole-rock geochemistry, mass balance calculations, Isocon analysis (Grant, 1986; 2005), petrography, electron microprobe analysis, SEM-EDS, and SEM-MLA.

2.3 Mineral indicators and geochemical vectors for gold mineralization

In samples that do not contain macroscopically-visible gold, it is useful to be aware of features that can be used to estimate gold concentrations. These are valuable for mine geologists especially when differentiating between lower grade ore and waste which is often challenging when working in wet and poorly lit conditions underground. This can be useful in a variety of grade control situations including but not limited to:

a) Identification of prospective ore zones in drill core prior to assay;
b) Estimating the grade of a face in order to facilitate further mine planning prior to receiving assay results; and
c) Estimating gold-grade in oversized material or mislabelled/unlabelled stockpiles.

Gold grade is divided into three groups in this thesis: High-grade (> 4 g/t Au), low-grade (1–4 g/t Au), and waste rock (< 1 g/t Au). Key mineralogical and textural indicators that correspond with each of these groups are identified. The distribution of material in each of these groups within auriferous alteration envelopes is also presented. These objectives are accomplished using whole-rock geochemistry, Isocon analysis (Grant, 1986; 2005), petrography, electron microprobe analysis, SEM-EDS, and SEM-MLA.

2.4 Source(s) of sulphur and the gold-bearing fluid

The source of the auriferous fluid responsible for mineralization at the Island Gold deposit is unclear. The fluids responsible for mineralization in Archean orogenic gold deposits may have been sourced from the mantle, cooling crustal felsic intrusive bodies, meteoric water or generated through metamorphism (e.g. Phillips and Groves, 1983; Hronsky et al., 2012; Xue et al., 2013; Tomkins, 2013).

Hydrosulphide complexes are believed to transport gold in hydrothermal fluids (Zhu et al., 2011) and, as a result, sulphide minerals are genetically associated with orogenic gold deposits (Goldfarb et al., 2005). Ratios of sulphur isotopes (^{32}S ^{33}S, ^{34}S, and ^{36}S) can be used to determine the source(s) from which the sulphur was derived and also constrain the temperatures of the fluid during infiltration (Xue et al., 2013; Lambert et al., 1984; Ohmoto and Rye, 1979). While most studies focus on $\delta^{34}S$ ratios, other isotopes of sulphur can be used in Archean deposits to track the source of sulphur due to the potential for mass-independent fractionation (MIF) in the Archean. MIF of sulphur is only known to occur due to ultraviolet photolysis reactions in the low oxygen atmosphere of the Archean (Farquhar et al., 2001; Pavlov and Kasting, 2002). These photochemical reactions cause the dissociation of atmospheric SO_2 to an oxidized species (SO_4^{2-} - negative $\Delta^{33}S$) and a reduced species (S_8 - positive $\Delta^{33}S$) (Farquhar and Wing, 2003). These sulphur species are then transferred to meteoric waters and due to differences in solubility, some depositional environments become enriched in S_8 while others are enriched in SO_4^{2-} (Maynard et al., 2013). As a result, some sedimentary rocks have dominantly positive $\Delta^{33}S$ sulphur while others have negative $\Delta^{33}S$ sulphur. Nonetheless, sulphur in or sourced from Archean sedimentary rocks often exhibits mass-independent fractionation (MIF) (Farquhar et al., 2000) where $\Delta^{33}S \neq 0$. Conversely, sulphur derived from post-Archean sedimentary rocks tends to show mass-dependent fractionation (MDF) (Farquhar et al., 2000) where $\Delta^{33}S \approx 0$. Similarly, juvenile sulphur derived from the Archean mantle (either directly or from igneous rocks of mantle parentage) also exhibits MDF (Farquhar et al., 2002; Xue et al., 2013) where $\Delta^{33}S \approx 0$. Non-zero $\Delta^{36}S$ values are also indicative of MIF (Farquhar and Wing, 2003).

Comparing the sulphur isotopes of sulphide minerals from ore zones and veins to other sulphide-bearing lithologies locally is conducted to determine the potential source(s) of sulphur. If the sulphides at the Island Gold deposit are found to have MIF sulphur, this indicates that the

sulphur was at the Earth's surface at some point prior to the gold mineralization event(s) which likely occurred between *c.* 2680 Ma and 2672 Ma (Jellicoe, 2019). Constraining the source of the gold-bearing fluid will improve the understanding of the geological history of the Island Gold deposit and could contribute to the knowledge of orogenic gold deposits as a whole.

2.5 Timing of gold mineralization

The age of gold mineralization at the Island Gold deposit has been bracketed by conducting geochronology on post-mineralization and pre-mineralization lithologies (Jellicoe, 2019). This study attempts to directly determine the age of gold mineralization by conducting an LA-ICP-MS geochronologic study of hydrothermally-altered and least-altered zircons from an ore zone. Altered zircons may show evidence of recrystallization, overgrowth, dissolution, and/or lead loss, which can be used to constrain the age of alteration and hence bracket the timing of gold mineralization (e.g. Schneider et al., 2012). The age of gold mineralization can help prioritize the exploration of structures and lithologies that pre-date this age as well as help target structures that were active during gold mineralization.

3.0 Methods

In this section, major lithologies at the Island Gold deposit are referred to based on their interpreted protoliths (Section 5.1): Quartz (± carbonate) veins (V_{GD}, V_1-V_2, and V_3), dacite, iron formation, gabbro, the Webb Lake stock, gabbro/lamprophyre, quartz diorite, silica-poor diorite–monzodiorite, and diabase–quartz diabase.

3.1 Sampling

Samples were taken from drill core, wall rock in mine workings, and outcrops on surface. For all of the samples described below, macroscopic weathering and other contaminants were removed from each sample using a rock hammer or diamond rock saw.

3.1.1 Least-altered samples

To evaluate the protoliths of the various intrusive and volcanic rocks, samples of least-altered rocks were taken from outside, the margins, and within the GLDZ that correspond with more altered samples. These least-altered samples may have been subject to minor alteration and, in most cases, have been metamorphosed to greenschist facies.

3.1.2 Alteration envelopes and mineral indicators

Samples were taken moving progressively away from gold-bearing quartz veins towards areas unaffected by alteration related to the auriferous veins. When possible, grab samples with little or no vein-related hydrothermal alteration were also taken from outside of the alteration envelopes to act as representative “least-altered” samples. When selecting samples of altered wall rock, visible quartz veins and veinlets were preferentially avoided. This systematic sampling procedure was performed for alteration envelopes hosted by each of the three major ore-hosting lithologies at Island Gold (dacite, gabbro, and the Webb Lake stock). Furthermore, in order to identify if the alteration changed with varying distance (parallel to the GLDZ) or elevation, this was also undertaken for multiple dacite-hosted alteration envelopes with varying locations within the deposit. Alteration envelopes at approximately the same depth at the eastern and western margins of the mine workings were sampled for comparison. In addition, a near surface alteration envelope and one of the deepest intersected envelopes were sampled. These two alteration envelopes were situated at approximately the same location in relation to the strike of

the GLDZ. An alteration envelope located at the approximate centre of current mine workings was also sampled. Sporadic sampling of multiple dacite-hosted alteration envelopes was also conducted between the eastern and western, and upper and lower margins of the deposit. These samples were taken from underground mine workings and drill core. When studying a specific alteration (alteration related to V_{GD} veins for example), alteration envelopes were typically selected to avoid areas where alteration related to a different alteration event (e.g. V_1-V_2 veins) was also affecting the same rock. This practice ensures that the effects of one alteration event are not mistaken for the effects of another.

3.1.3 Geochronology

To bracket the age(s) of gold mineralization at the Island Gold deposit, a sample of an intensely hydrothermally-altered dacite from an ore zone was collected. A sample of a least-altered equivalent from outside or at the outer margin of the same auriferous alteration envelope was also collected. Both samples were collected from underground mine workings on the same level. The least-altered sample was taken from a cross-cut, while the altered sample was collected from an attaching drift.

3.1.4 Sulphur isotopes

Sulphide-rich samples of altered wall rock were taken from ore-zones hosted by each of the three main ore-hosting lithologies (dacite, gabbro, and the Webb Lake stock). Multiple samples from dacite-hosted ore zones distributed throughout the extent of the deposit were also collected. Furthermore, each type of auriferous quartz vein (V_{GD}, V_1 and V_2 as identified in Jellicoe, 2019) was sampled. These sulphides, located in gold-bearing quartz veins and their associated alteration envelopes, are from the ore zones at Island Gold and are genetically linked to gold mineralization. Sulphide-rich iron formations and the silica-poor diorite-monzodiorite were also sampled. Samples were taken from underground workings, drill core, and surficial outcrops.

3.2 Whole-rock geochemistry

A total of 94 samples were prepared at the University of Waterloo and then shipped to Activation Laboratories Ltd. (Actlabs) in Ancaster, Ontario for crushing and whole-rock

geochemical analyses. Crushing was conducted using a steel jaw crusher to a minimum of 90% (< 2 mm). A mechanically split portion (riffle) was then pulverized in a mild steel mill until > 95% of the sample was less than 74 μm. This pulverization method could result in the potential addition of a maximum of 0.2% Fe but does not introduce Ni or Cr. Cleaner sand was used between each sample (Actlabs, 2018a) to avoid cross contamination.

The following Actlabs packages/analyses were used: 4Lithores (4B and 4B2 Research)-Lithium Metaborate and Tetraborate Fusion-ICP and ICP/MS, Quant, 4F-B-PGNAA, 4F-CO2 Infrared, 4F-C, S Infrared, 4F-Hg Cold Vapour FIMS (HGFIMS), 4F-FeO Titration, Ultratrace 2-Aqua Regia-ICP-ICP/MS (As-Bi-Se-Sb-Te), Ultratrace 4-"Near Total" Digestion-ICP/MS (certain elements; Table 1), 1C-Exp 2-Fire Assay (Au, Pd, Pt), 1A3-Au Fire Assay-Gravimetric (if needed), Cu-Zn-Pb-Ni-As (if needed), 1A2-Au Fire Assay (Only sample numbers > T213; Appendix N) (Actlabs, 2018b). Table 1 summarizes the analytical techniques used to obtain concentrations of each analyte. In some cases, the concentration of the same analyte was measured using multiple methods. In Table 1, analyte-method pairs in bold were selected for use in this thesis. Whole-rock geochemical results, including those pertaining to QA/QC materials, were released as an Open File Report (Ciufo et al., 2019) and are also reported in Appendix N and Appendix O.

Concentrations of major oxides and select trace elements (Table 1) were determined via lithium metaborate-tetraborate fusion followed by inductively coupled plasma atomic emission spectrometry (FUS-ICP). Samples were fused in an induction furnace after being mixed with lithium metaborate and tetraborate. The molten product was then dissolved in a solution of 5% nitric acid. Concentrations of analytes were then determined using Inductively Coupled Plasma Atomic Emission Spectrometers (Varian Vista 735 ICP or Thermo Jarrell-Ash ENVIRO II ICP). Seven CANMET and USGS certified reference materials were used to calibrate these spectrometers (Actlabs, 2018b). Loss on ignition (LOI) was determined by weighing the sample before and after roasting (Actlabs, 2018b).

Most trace elements concentrations were determined by fusing with lithium metaborate and tetraborate, diluting, and then analyzing with a Perkin Elmer Sciex ELAN 6000, 6100 or 9000 inductively coupled plasma mass spectrometer (recalibrated after every 40 samples; Actlabs, 2018b; FUS-MS).

Au, Pd, and Pt concentrations were determined via fire assay and inductively coupled plasma mass spectrometry (FA-MS). Litharge, silica, borax and soda ash are combined with the 30 g sample in a crucible. Ag is also added as a collector. Over the course of 60 minutes, the mixture is then heated in an assay furnace. The molten slag is then poured into a mould. The lead button from the base of the mould is transferred to a cupel which absorbs the lead from the bead. A hot nitric and hydrochloric acid solution is used to digest the bead and, after cooling, a Perkin Elmer Sciex ELAN 6000, 6100, or 9000 ICP/MS is used to determine the concentrations of Au, Pt, and Pd (Hoffman et al., 1998; Hoffman et al., 2002; Actlabs, 2018b). Samples returning Au concentrations greater than 30 ppm were repeated using the same fire assay process but with a gravimetric finish (FA-GRA). The gravimetric finish involves separating the Au from the Ag in the bead using nitric acid. The gold is then weighed gravimetrically (Hoffman et al., 1998; Actlabs, 2018b). For all samples with sample numbers greater than 213, gold concentrations were determined via the same fire assay process but with an atomic absorption finish (FA-AA; Appendix N). The bead is dissolved in aqua regia prior to being analyzed for gold via atomic absorption (Hoffman et al., 1998; Actlabs, 2018b). This technique was used to reduce cost, and these ten samples have low gold concentrations (< 0.1 ppm; Appendix N).

To determine the concentration of As, Bi, Sb, Se, and Te, aqua regia inductively coupled mass spectrometry (AR-MS) was used. Aqua regia is used to digest a 0.5 g sample for two hours. After dilution, the solution is analyzed using a Perkin Elmer SCIEX ELAN 6000, 6100, or 9000 ICP/MS (Actlabs, 2018b).

FeO was determined via titration (TITR) in an open system using a cold acid digestion of hydrofluoric acid and ammonium metavanadate in an open system. After digestion, ferrous ammonium sulphate is added. Potassium dichromate is used as the titrating agent. For samples with S concentrations greater than 10%, a hot digestion method is used instead (Wilson, 1955; Actlabs, 2018b).

The concentrations of certain elements (Table 1) were determined via “near total” digestion mass spectrometry (TD-MS). Four acids were used to digest a 0.25 g sample. First, hydrofluoric acid was used followed by nitric and perchloric acids. The sample was then dried by heating. Hydrochloric and nitric acid was used to bring the sample back into solution. Certain resistant minerals may not have been completely digested. Partial volatilization of As, Cr, and Sb

may have also occurred. A Perkin Elmer Sciex ELAN 6000, 6100, or 9000 ICP/MS was then used to determine the concentration of elements of interest (Actlabs, 2018b).

In order to measure the concentration of CO_2, a 0.2 g sample was first decomposed using an ELTRA CW-800 (directly releasing CO_2). This is conducted in a pure nitrogen environment within a resistance furnace at 1000°C. Prior to the detection of CO_2, H_2O was removed in a moisture trap. The concentration of CO_2 was determined via an infrared (IR) detector (Actlabs, 2018b).

Carbon and sulphur concentrations were determined via the following steps. A 0.2 g sample and accelerator material were subject to combustion in an induction furnace. SO_2 and CO_2 concentrations were measured via infrared (IR) detectors. Either a CS-2000 or an Eltra CS-800 was used in this process (Actlabs 2018b).

Boron concentrations were determined via prompt gamma neutron activation analysis (PGNAA). First, a 1 g sample is placed into a thermalized beam of neutrons. The doppler broadened prompt gamma ray was measured at 478 KeV with a GE detector and compared to the certified reference materials used for system calibration (Actlabs, 2018b).

The concentration of mercury is determined via cold vapour flow injection mercury technique (1G/AR-FIMS) using a Perkins Elmer FIMS 100. First, aqua regia was used to leach soluble compounds. An aliquot of the resulting solution is combined with a solution of potassium permanganate. The flow injection cold vapour mercury technique is then performed and the concentration of Hg is determined in the absorption cell by the absorption of light at 253.7 nm (Actlabs 2018b). Excluding Appendix N, Appendix O, and Appendix Q, concentrations below detection limit were replaced with values that are half of the detection limit in this thesis.

Table 1. *Analytical methods used at Actlabs to obtain concentrations of chemical species. Bolded analyte-method pairs were selected for use in this thesis while those that are non-bolded are not used. 3.2.1 Whole-rock geochemistry quality assurance / quality control (QA/QC)

Quality assurance/quality control procedures undertaken for the validation of geochemical data are detailed in this section. Concentrations of chemical species in QA/QC materials in Appendix N and Appendix O are from Activation Laboratories Ltd. Measured concentrations of chemical species in lab (Actlabs)-provided reference materials, duplicates (duplicate analyses), and blanks used for geochemical QA/QC in this thesis are part of an open file report (Ciufo et al., 2019) and are also included in Appendix O. Measured concentrations of chemical species in NRCan-provided reference materials (STPL), that were also used for geochemical QA/QC in this thesis, are included in Appendix N. Based on analysis of these results (Sections 3.2.1.1 and 3.2.1.2; Appendices P to R), the geochemical data used in this thesis is considered fit for purpose. Concentrations of some chemical species determined via certain methods were not used in this thesis (besides being reported in the Appendix) and these analyte-method pairs are indicated in Appendices P and R. The term "standard(s)" is often used to refer to reference material(s) in this thesis.

3.2.1.1 NRCan-provided reference materials

A total of 10 external pulp standards (seven "STPL-BAS" standards and three "STPL-PML-53" standards) provided by Natural Resources Canada were included with samples sent for geochemical analyses. This equates to a 9.4 : 1 sample to standard ratio. Both accuracy and precision are assessed separately for each of the two standard types. Accuracy is assessed for

each method-analyte pair and standard type by calculating percent relative difference using the following equation from Jenner (1996) and Piercey (2014) with modified variables:

$$RD = 100 * \frac{Avg - Std}{Std}$$

where 'RD' is percent relative difference; 'Avg' is the average of the measured values obtained in this study from analyses of the standard; and 'Std' is the 'known/actual' value for the standard.

The average of the measured values from previous analyses of each standard type for each analyte-method pair (Appendix R; Natural Resources Canada, personal communication, 2018) are used for the known values. The known average value for the STPL-BAS standard was calculated from 50 analyses while the known average value for STPL-PML-53 was calculated from 48 analyses (Appendix R; Natural Resources Canada, personal communication, 2018).

Precision is assessed for each analyte-method pair and standard type by determining percent relative standard deviation using the following equation from Jenner (1996) and Piercey (2014) with modified variables:

$$RSD = 100 * \frac{Std\ Dev}{Avg}$$

where 'RSD' is percent relative standard deviation; 'Std Dev' is the standard deviation of the measured values obtained in this study from analyses of the standard; and 'Avg' is the average of the measured values obtained in this study from analyses of the standard.

The results of QA/QC analysis of external standards are tabulated in Appendix R. It is indicated whether or not the average measured value for an analyte-method pair is near the detection limit (within ten times the detection limit (< 10x DL)). In many cases, RD or RSD values indicative of inaccuracy or imprecision are explained by concentrations of certain analytes being close to detection limit (Appendix R). Results from analyte-method pairs that were not used in this thesis are also indicated (Appendix R). Overall, results are consistent with historical analyses of these standards (Appendix R). For this geochemical dataset, the analysis of duplicates and lab-provided standards is recommended to quantify precision and accuracy

(Section 3.2.1.1; Appendix P) because it is likely that they can better represent true precision and accuracy than NRCan-provided standards. This is because the lab-provided standards include certified reference materials, are provided at various concentrations for a given analyte, and have a higher frequency of insertion than the NRCan-provided standards. Duplicate analyses are of samples submitted for this thesis from the Island Gold deposit. Subsequently, they will better reflect the analytical precision of samples from this dataset because they are from this location.

3.2.1.2 Lab-provided reference materials, duplicates, and method blanks

Standards, duplicates (duplicate analyses), and method blanks, provided by Actlabs as part of their quality control procedure, were also assessed (Appendix O). The frequency of each of these internal controls varies for each analyte-method pair and are summarized in Appendices P, Q, and R. Lab-provided standards include certified reference materials and in-lab standards that are traceable to certified reference materials (Actlabs, 2018b). Statistics to quantify precision and accuracy of data for each analyte-method pair are also displayed in these appendices. Detection limits (DL) and limits of quantification (LOQ; three times the detection limit) for each analyte-method pair are summarized in Appendix P.

Lab-provided standards are used to quantify accuracy. Average relative difference is determined for each method-analyte pair using the formula modified from Skoog and West (1963):

$$RD = \frac{\sum_{i=1}^{n}(100 * (Meas_i - Cert_i)/Cert_i))}{n}$$

where RD is average percent relative difference, '$Meas_i$' is the measured value for the i^{th} standard for a given analyte-method pair, '$Cert_i$' is the corresponding 'known/actual' value for the i^{th} standard; and 'n' is the total number of standards analyzed for a given analyte-method pair.

The results of QA/QC analysis of lab-provided standards are tabulated in Appendix P. The number of standards analyzed that have known values less than 10 times detection limit is noted for each analyte-method pair. Concentrations of LOI and Fe_2O_3 were not determined in lab-provided standards and as a result the accuracy of LOI and Fe_2O_3 are not quantified in Appendix P. Excluding LOI and Fe_2O_3, 82% of analyte-method pairs used in this thesis have

average RD values between -10 and 10%. Average RD values for all analyte-method pairs used in this thesis range from -48.4 to 77.7%. In many cases, average RD values indicative of inaccuracy for certain analyte-method pairs appear to be due to numerous standards having known values that are close to detection limit for these analytes. With the exception of As (-20.5%; AR-MS), Cr (-13.6%; TD-MS), and Sb (-48.4%; AR-MS), all analyte-method pairs used in this thesis with average RD values outside of the -10 to 10% range each have multiple standards with known values of their respective analyte below 10 times the detection limit (Appendix P).

Lab duplicates are used to assess precision by determining the average coefficient of variation equation as recommended in Stanley and Lawie (2007) and Abzalov (2008; 2011) and modified from Piercey (2014):

$$CV_{avg} = 100 * \sqrt{\frac{2}{n} * \sum_{i=1}^{n} (\frac{(A_i - B_i)^2}{(A_i + B_i)^2})}$$

where 'CV_{avg}' is the average coefficient of variation (%) for a given analyte-method pair; 'A_i' is the original measured value for i^{th} duplicate pair; 'B_i' is the corresponding duplicate measured value for i^{th} duplicate pair; and 'n' is the total number of duplicate pairs.

The results of QA/QC analysis of internal lab duplicates are tabulated in Appendix P. The number of measured duplicate values that are less than 10 times detection limit is also noted for each analyte-method pair (Appendix P). No duplicate analyses of Au concentrations determined via FA-GRA were conducted and as a result the precision of this analyte-method pair is not quantified in Appendix P. Excluding Au (FA-GRA), 79% of analyte-method pairs used in this thesis have average CV values ranging from 0 to 10%. Average CV values for all analyte-method pairs used in this thesis range from 0 to 59.6%. In most cases, average CV values of analyte-method pairs indicative of imprecision appear to be due to duplicates with concentrations of respective analytes that are close to detection limit. With the exception of B (13.8%; PGNAA), Cr (18.5%; TD-MS), and Ni (11.6%; TD-MS), all analyte-method pairs with average CV values above 10% that were used in this thesis have multiple duplicates with measured

values of their respective analyte below 10 times the detection limit (Appendix P). Results from analyte-method pairs that were not used in this thesis are also indicated (Appendix P).

A summary of the analysis of method blanks for each method-analyte pair is located in Appendix Q. Addition comments are included if blanks return measured concentrations that are higher than the LOQ (three times the detection limit; Appendix Q). The analyte-methods pairs where analysis of blank(s) returned concentrations higher than LOQ include As (AR-MS), Bi (AR-MS), Au (FA-MS), Cr (TD-MS), Mn (TD-MS), and Zn (TD-MS). However, with the exception of Mn (TD-MS) and one As blank analyzed via AR-MS, concentrations determined via analysis of these blanks are relatively close to detection limit (Appendix Q). Of these six analyte-method pairs, concentrations of Mn determined via (TD-MS) were not used in this thesis while concentrations determined via the other five analyte-method pairs were used. No lab-provided method blanks were analyzed for C, Fe_2O_3, LOI, or S.

3.2.2 Isocon diagrams

Isocon diagrams introduced in Grant (1986) based on the equations in Gresens (1967) are used to determine and display chemical enrichments and depletions resulting from alteration. Isocon diagrams in this thesis were created using EASYGRESGRANT which is a Microsoft Excel spreadsheet developed by López-Moro (2012). These diagrams involve plotting the concentration of elements (ppm) and oxides (mass percent) in the altered sample (C_A) against the concentration of the corresponding elements and oxides in the less-altered sample (C_{LA}). The Isocon is a straight line through the origin that defines no relative change in mass (Grant, 1986). Chemical species that plot below the Isocon are assumed to have been lost during alteration while species plotting above the Isocon are gained (Grant, 2005). The slope of the Isocon is determined by the line of best fit (linear regression) through inferred immobile chemical species. Immobile species will have similar slopes (C_A/C_{LA}) (Grant, 2005) and immobile elements for each Isocon diagram were selected based on the clustering of slope values. Species commonly identified and used as immobile elements in this study include Al_2O_3, Cr, Dy, Er, Gd, Hf, Ho, Lu, Nb, Sc, Ta, Tb, Th, TiO_2, Tm, Y, Yb, and Zr. A number of studies also suggest that these elements and oxides are relatively immobile during alteration (e.g. Winchester and Floyd, 1977; Pearce, 1996; Hastie et al., 2007). Based on the clustering of slopes, each Isocon diagram used a number of immobile elements from this list and the immobile elements selected for each Isocon

diagram are summarized in Appendix S. To confirm that choice of immobile elements for each Isocon diagram is appropriate, a classical least-squares regression method is used. A correlation coefficient of greater than 0.999 is considered acceptable and is achieved for all Isocon diagrams. Constant mass and constant volume lines are also plotted for each diagram. Samples absent of macroscopically visible quartz veins were preferentially selected for Isocon analysis.

This method of selecting immobile elements that may vary from diagram to diagram minimizes a number of issues related to static immobile element selection. For example, an element may be immobile in circumstances of weak alteration and therefore can be used as an immobile element. However, this element may become mobile during strong alteration and should no longer be used as an immobile element. Furthermore, heterogeneities in samples can result in non-alteration-related apparent enrichments or depletions in certain elements even if these elements are immobile. For example, a less-altered sample with a large zircon grain ($ZrSiO_4$) results in the altered sample having comparatively less zirconium when compared to the less-altered sample which does not contain this grain. In this example, this is due to mineralogical heterogeneity unrelated to alteration and is analogous to the 'nugget effect'. If zirconium was used as an immobile element in this diagram, it would skew the slope of the Isocon line in this diagram but remains a valid immobile element choice for other altered/least-altered pairs. In many cases, the same immobile elements are selected between Isocon diagrams. Determining immobile elements on a case-by-case basis based on the clustering of slopes is more time consuming but prevents these errors. In the example above, zirconium will appear depleted but it will not affect the slope of this Isocon diagram and subsequent interpretations of enrichment or depletion for other chemical species. Multiple altered/less-altered pairs and associated Isocon diagrams are created and interpreted and only chemical species that are consistently enriched or depleted are deemed to be gained or lost, respectively. Therefore, non-alteration-related heterogeneities in a sample that result in pseudo enrichments and depletions are identified and discarded.

Chemical species that are selected as immobile for any given Isocon diagram are considered to be neither enriched nor depleted. In rare cases, certain chemical species are below detection limit in both the altered and least altered sample (most commonly: Ag, As, Mo, Se, Te, and Tl). For an altered/least-altered pair where this is the case, these chemical species are not plotted on its respective Isocon diagram. In addition, mass gains and losses for these chemical

species are considered inconclusive for that altered/less-altered pair. However, these chemical species can still be considered consistently gained or lost when examining the same type of alteration if other altered/less-altered pair(s) (where the concentration of that chemical species is not below detection limit for both samples in a pair) exhibit all gains or all loses of that chemical species, respectively. Chemical species that are determined to be gained or lost based on the examination of altered/least-altered pairs (as discussed above) are referred to as consistent gains and consistent losses in this thesis.

In order to quantify the magnitude of enrichment, mass balance calculations (discussed in Section 3.2.4) are also conducted after alteration groupings (Section 3.2.3) were established using the results from Isocon analysis. These mass balance calculations compare enrichments/depletions of chemical species in samples classified as strongly, moderately, weakly, and least-altered using static immobile element selection. Resulting enrichments and depletions from this mass balance method, in which the same immobile elements were selected for calculations, can be compared to the enrichments and depletions determined from the graphical Isocon method, in which different immobile elements were selected for each diagram on a case-by-case basis.

Constant volume lines are calculated using density values determined using the methods outlined in Section 3.7. In some Isocon diagrams, select concentrations of chemical species are arbitrarily scaled to avoid stacking/overlap. Arbitrarily scaling concentration data can change the slope of the best-fit Isocon (Mukherjee and Gupta, 2008.). To avoid this, the same Isocons (with identical slopes) are used in corresponding scaled and unscaled diagrams. In other words, the slopes of Isocons are determined prior to rescaling of any chemical species. For display purposes, some chemical species that are not discussed and are not consistently enriched or depleted in multiple altered/less-altered pairs are removed. Some elements included in the geochemical package (Be, Cd, Hg, In, Pt, Pd, Sn) were not examined via Isocon analysis because their concentrations are below detection limit for most samples.

3.2.3 Alteration strength groupings

In order to compare variably-altered samples from alteration envelopes throughout the deposit, it was necessary to group samples based on strength of alteration. As a result, a preliminary geochemical study was conducted to determine chemical proxies for alteration.

Preliminary study of altered and least-altered pairs yielded that potassium oxide (K_2O) and sulphur (S) consistently correlate with increasing alteration in all of the main ore-hosting lithologies (dacite, gabbro, and the Webb Lake stock; Table 4). These chemical species are also present in relatively low concentrations in the least-altered samples of these lithologies and are enriched significantly due to auriferous quartz vein-related alteration. These characteristics made them ideal candidates to be chemical proxies for strength of alteration.

Four alteration groups (Strongly-altered, moderately-altered, weakly-altered and least-altered) are defined based on concentrations of S and K_2O for each lithology (Figure 6), qualitative estimates of alteration strength, and proximity to gold-bearing quartz veins. The proposed groups correlate well with the estimated strength of alteration determined by macroscopic and microscopic examination. Boundaries between groupings were determined by averaging the chemical compositions of the nearest two points on either side of a proposed boundary. On Figure 6, vertical boundaries were determined by averaging K_2O concentrations while horizontal boundaries were determined by averaging S concentrations. Boundaries between alteration strength groupings are summarized in Table 2. These quantitative alteration strength groupings were only applied to select samples of dacite, gabbro, and the Webb Lake stock (the major pre-gold mineralization lithologies) that were sent for whole-rock geochemical analysis. For rocks and samples (including other lithologies) not classified via this quantitative method, these terms (e.g. least-altered, weakly-altered) are occasionally used to indicate the approximate strength of alteration based on qualitative estimates.

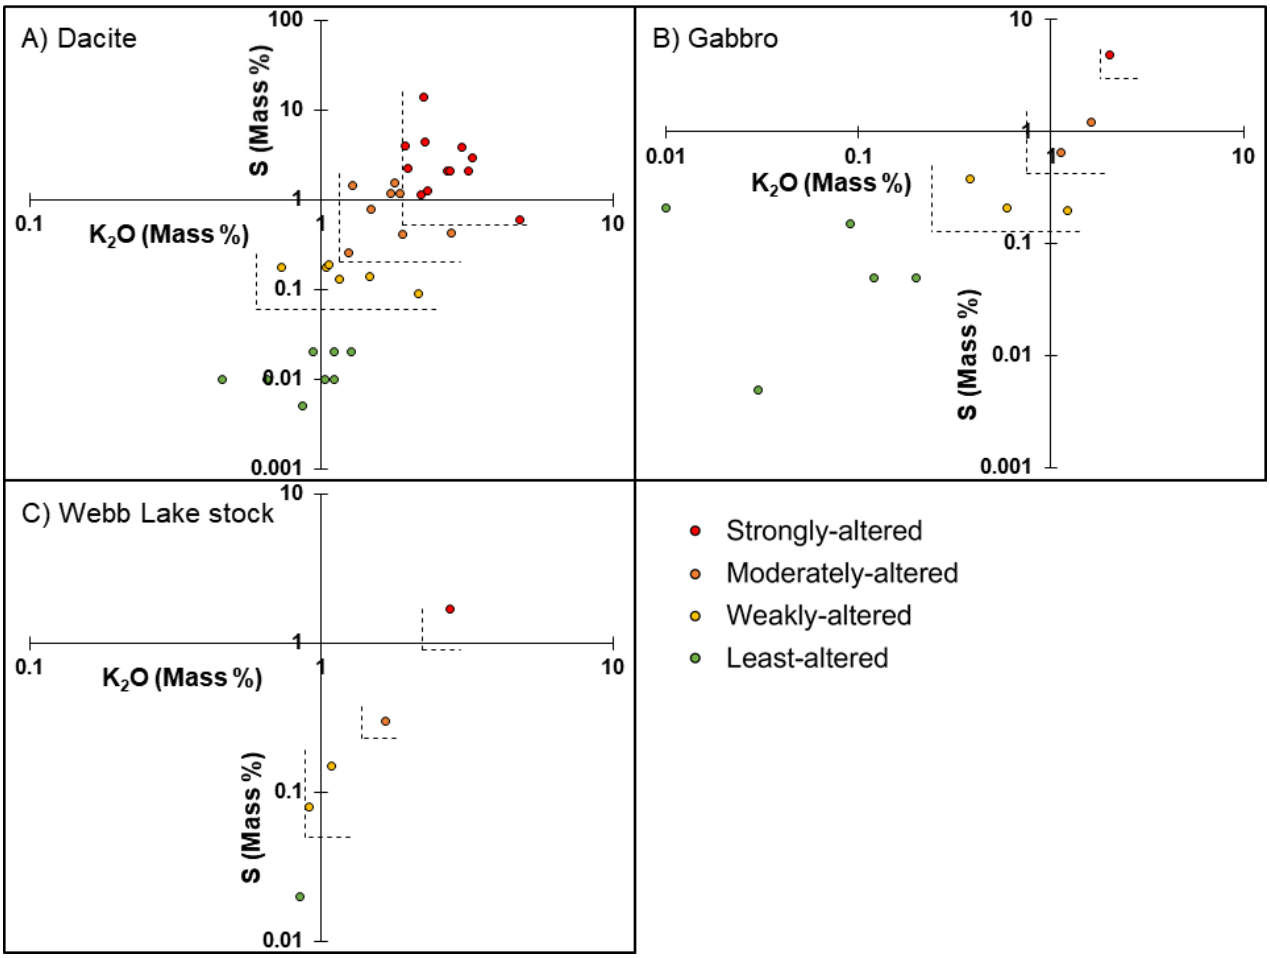

Figure 6A–C. *Variably-altered samples of the three major ore-hosting lithologies plotted on separate K_2O vs. S plots. These diagrams are used to quantify the strength of alteration by subdividing samples into groups based on the K_2O and S enrichment. Boundaries between alteration groups are indicated using dashed lines and quantified in Table 2. Concentrations below detection limit are replaced with the detection limit for display purposes. A) Dacite: Strongly-altered (T56, T58, T71, T72, T86, T90, T105, T113, T157, T158, T162, T188), moderately-altered (T17, T20, T73, T85, T88, T114, T156, T186), weakly-altered (T13, T59, T115, T117, T118, T184), and least-altered (T8, T11, T65, T116, T154, T164, T183, T241). B) Gabbro: Strongly-altered (T142), moderately-altered (T141, T140), weakly-altered (T19, T87, T139), and least-altered (T14, T80, T89, T182, T200). C) Webb Lake stock: Strongly-altered (T195), moderately-altered (T194), weakly-altered (T6, T193), and least-altered (T192).*

Table 2. *Boundaries between alteration strength groupings for each of the main ore-hosting lithologies.*

		K_2O (wt%)	S (wt%)
Dacite	Strongly-altered	> 1.91	> 0.52
	Moderately-altered	1.15-1.91	0.20-0.52
	Weakly-altered	0.73-1.15	0.06-0.20
	Least-altered	< 0.73	< 0.20
Gabbro	Strongly-altered	> 1.82	> 3.02
	Moderately-altered	0.75-1.82	0.43-3.02
	Weakly-altered	0.24-0.75	0.13-0.43
	Least-altered	< 0.24	< 0.13
Webb Lake stock	Strongly-altered	> 2.22	> 0.99
	Moderately-altered	1.38-2.22	0.23-0.99
	Weakly-altered	0.88-1.38	0.05-0.23
	Least-altered	< 0.88	< 0.05

3.2.4 Mass balance calculations

In order to quantify the magnitude of gains and losses of chemical species due to alteration, mass balance calculations are performed. These calculations were conducted using an equation from Grant (1986) with modified variables:

$$\Delta C/C_{LA} = (inverse\ of\ Isocon\ slope) * (C_A/C_{LA}) - 1$$

where C=concentration, C_A=concentration in altered sample, C_{LA}=concentration in less-altered sample.

Gains and losses of chemical species were calculated for samples classified under each alteration strength grouping relative to less-altered samples. These calculations were performed separately for each lithology altered by V_1-V_2 veins. They were also conducted separately for dacite altered by V_{GD} veins. If multiple samples classified under a certain alteration grouping were present, their compositions were averaged. The chemical species that were frequently selected as immobile during Isocon analysis for a specific lithology were used as immobile elements for all mass balance calculations for that lithology. The slope of each Isocon was determined by averaging the values C_A/C_{LA} for each immobile element.

One sample of gabbro/lamprophyre altered by a V_3 vein, one sample of silica-poor diorite–monzodiorite altered by V_3 veins, and one dacitic sample subject to non-auriferous carbonate-sericite alteration were sampled. Due to the limited sampling of the alteration associated with V_3 veins and this non-auriferous carbonate-sericite alteration, mass balance calculations were performed using the altered sample and a corresponding representative less-altered sample for each lithology. Immobile elements used in the corresponding Isocon diagram for each altered/less-altered pair were used for these calculations. The selection process for immobile elements for Isocon diagrams is discussed in Section 3.2.2. The slope values for Isocons used in these mass balance calculations are the same as the slope of the Isocon displayed in each corresponding Isocon diagram. The calculation of slope values for Isocon diagrams are also discussed in Section 3.2.2. Certain chemical species included in the geochemical package used for this thesis (Be, Cd, Hg, In, Pt, Pd, Sn) were not included in any mass balance calculations because their concentrations are below detection limit for most samples.

3.3 Petrography and point-counting

Billets were cut using a rotary diamond saw from select samples and sent to Vancouver Petrographics Ltd. to be made into standard-sized (27 x 46 mm) polished thin sections for petrographic study. A total of 139 polished thin sections were created. Detailed transmitted and reflected light petrography and point-counting were conducted using a Nikon Eclipse LV100POL to identify minerals and textures. A Nikon Digital Sight DS-Fi2 camera coupled with NIS Elements Imaging Software was used to take most photomicrographs. In order to quantify mineral proportions, a thin section was subdivided into a 27-point by 15-point grid composed of 405 equally-spaced points. At each of these points, the mineral directly under the microscope crosshairs was identified and recorded. The mineral counts for each thin section were then normalized to 100%. Mineral modal proportions, in area percent, are assumed to be approximately equivalent to volume percent in this thesis. All point-counting data is presented in Appendix E.

3.4 Scanning electron microscopy with energy dispersive spectroscopy (SEM-EDS)

An SEM-EDS at the Environmental Particle Analysis Laboratory (University of Waterloo) was used to identify minerals in polished thin sections that could not be identified using traditional reflected and transmitted light microscopy. This device is a Hitachi TM3000 Table-top SEM coupled with a Bruker QUANTAX 70 EDS. It was also used for microscopic imaging. Polished thin sections were affixed to the stage using double-sided carbon tape.

3.5 Scanning Electron Microscope Mineral Liberation Analyser® (SEM-MLA)

SEM-MLA techniques were employed for mineral identification and determining mineral proportions for five variably-altered samples taken from a dacite-hosted alteration envelope (Appendix F). It is challenging to precisely determine the proportions of fine-grained quartz and feldspars in the volcanic rocks using transmitted light microscopy. As a result, SEM-MLA was used to identifying how the modal proportions of quartz and feldspar in dacitic rocks vary with changing alteration intensity. These analyses were conducted by staff at the Bruneau Centre's SEM-MLA Research Lab (Memorial University). The FEI MLA 650F SEM was used for this analysis. It is equipped with a Bruker electron backscatter diffraction system (EBSD) and an HKL Technology high throughput energy dispersive x-ray (EDX) system (CREAIT Network,

2018). The MLA software uses this equipment for the quantitative evaluation of a variety of characteristics including modal mineralogy, mineral associations, density distribution, mineral liberation, and grain sizes. It does this by automating imaging, movement of the stage, and X-ray acquisition of data (CREAIT Network, 2018). SEM-MLA thin section-scale images were also provided by this lab and feature false colours to help visualize changes in mineralogy (Appendix G; Figure 18). Mineral modal proportions, in area percent, (Appendix F) are assumed to be approximately equivalent to volume percent in this thesis.

3.6 Electron microprobe

Six thin sections were selected for microprobe analysis at the Electron Microprobe Laboratory which is part of the Earth and Planetary Material Analysis Laboratory at Western University. These thin sections consisted of altered and less-altered pairs from a dacite-hosted, a gabbro-hosted, and a Webb Lake stock-hosted alteration envelope. A JEOL JXA-8530F field emission electron microprobe was used to conduct these analyses. This machine is equipped with a scanning electron microscope with energy-dispersive X-ray spectroscopy (SEM-EDS) which was used to quickly identify minerals and help select locations for wavelength-dispersive X-ray spectroscopic (WDS) analysis. WDS was used to acquire quantitative chemical data for key primary, metamorphic, and/or alteration-derived minerals. These minerals include biotite, white mica, chlorite, plagioclase, and carbonates. The following elements were detected: Si, Al, Ti, Na, Ca, K, Fe, Mg, Mn, F, and Cl. For carbonate minerals, C concentrations were also measured. Microprobe data is located in Appendix H. The microprobe was calibrated differently depending on the type of mineral being analysed. Three configurations were used for analyses of certain minerals and these configurations are summarized in Appendix I.

Atoms per formula unit (apfu; Appendix H) were calculated based on the following number of oxygens for each mineral: biotite (22), chlorite (28), white mica (11), and plagioclase (8). H_2O values used in apfu calculations for biotite were calculated using the methods outlined in Tindle and Webb (1990). Biotite formulae are calculated using a Microsoft Excel spreadsheet by Andrew G. Tindle (Tindle, 2018a). Chlorite mineral formulae are calculated assuming full site occupancy when determining OH, Fe^{3+} and Fe^{2+} values. Chlorite formulae are calculated using an Excel spreadsheet program by Andrew G. Tindle (Tindle, 2018b). White mica formulae are calculated assuming all iron is ferrous using an Excel spreadsheet by John Brady (Brady,

2018b). Plagioclase formulae are calculated using an Excel spreadsheet by John Brady (Brady, 2018a). Mole proportions of Mg, Fe, and Ca were used to determine proportions of magnesite, siderite, and calcite for plotting on MSC ternary diagrams. These mole proportions were calculated for carbonate minerals assuming total iron is ferrous (Appendix H).

3.7 Density

The Archimedes method was used to determine the densities of certain samples which were used to plot constant volume lines on Isocon diagrams. The Archimedes Principle states that the buoyancy force equals the weight of the water the sample displaces. If the weight of the sample in air (m_a) and the weight of the sample in deionized water (m_w) are determined, the following equation can be used to determine the density of the sample (ρ_s). The density of deionized water (ρ_w) is assumed to be 0.9982 g/cm^3 at 20°C (Weast, 1972).

$$\rho_s = \frac{m_a}{m_a - m_w} * p_w$$

A representative piece of each sample selected for density measurement were first washed with deionized water and allowed to dry. These samples range in weight from 9 to 32 grams. A beaker was filled with deionized water. The suspension apparatus was set on the scale with the basket made of fishing line suspended in the beaker of water. The following steps were then repeated between each sample. First, the sample was placed on the scale and the weight in air (m_a) was recorded. The sample was then placed in the basket suspended in the water-filled beaker and the weight was recorded (m_w). This process was repeated for each sample. The scale used is a Sartorius Quintix124-1S which has a capacity of 120 g and a readability of 0.0001 g.

To assess accuracy and precision, the density of three known mineral samples (two quartz crystals and one apatite crystal) were measured after every ten samples. Quartz has an ideal density of 2.65 g/cm^3 (Mursky and Thompson, 1958) but is often noted to range from 2.5-2.7 g/cm^3 (e.g. Telford et al., 1990). The density of apatite ranges from 3.16 to 3.22 g/cm^3 (Mason and Berry, 1968). Due to microscopic inclusions or other imperfections in these mineral samples such as voids, measured densities may vary slightly from true densities. Average relative difference is used to assess accuracy using the RD equation described in Section 3.2.1.1. The RD

values determined from measurements of the two quartz crystal standards were -0.246% and -0.470%. All measurements of apatite fell within the apatite density range outlined above. Relative standard deviation is used to assess precision of repeat analysis of standards using the RSD equation described in Section 3.2.1.1. RSD values range from 0.192 to 0.227. To further assess precision, the density of seven samples were analysed a second time. All duplicate measurements fall within 2% precision control lines (Appendix J). Based on this QA/QC analysis, density measurements are considered fit for purpose. All the results of QA/QC analysis are summarized in Appendix J.

3.8 Sulphur isotopes

3.8.1 University of Waterloo – Environmental Isotope Laboratory

Twenty select samples (Appendix K) were crushed at Actlabs using the same methodology outlined at the beginning of Section 3.2. These powdered samples were sent to the University of Waterloo-Environmental Isotope Laboratory to determine the $\delta^{34}S$ value for each. The analytical process is summarized below (EIL, 2017). Samples and standards were weighed into tin capsules that also contained a few mg of Nb_2O_5 which was added to aid in the conversion to SO_2 gas. A 4010 Elemental Analyzer (Costech Instruments) coupled with a Isochrom (Micromass UK) Continuous Flow Isotope Ratio Mass Spectrometer (CFIRMS) was used for the conversion of samples to a gas (through combustion) and isotopic analyses. The $\delta^{34}S$ values are the corrected ratios of $^{34}S/^{32}S$, measured against the Vienna-Canyon Diablo Troilite (VCDT) meteorite reference standard (EIL, 2017).

A number of international reference materials and in-house standards (calibrated using international reference materials: NBS-127, NBS-123, IAEA-SO-5, IAEA-SO-6, IAEA-S1 to-S3) were used to monitor data quality and make corrections. Sulphate standard reference materials are run with sulphate samples and sulphide standard reference materials are run with sulphide samples. Every 4^{th} to 6^{th} sample is repeated. At least 20% of the analyzed samples are standard reference materials which were used to normalize data and quantify accuracy and precision. They are also used to assess mass spectrometer drift or linearity issues during analysis. Based on this quality assurance-quality control protocol, an error of ±0.3‰ $\delta^{34}S$ for standards is required (EIL, 2017). Results of this analysis (Appendix K) were used to help select samples to be sent to the University of Maryland for further isotopic analysis.

3.8.2 University of Maryland – Stable Isotope Laboratory

Ten select samples (Appendix L) were crushed using a steel pestle and mortar and sieved through a 2 mm mesh. Between each sample, the pestle, mortar, and sieve were cleaned thoroughly by washing and rinsing with water followed by ethanol. Pyrite grains were hand-picked from the material that passed through the 2 mm sieve with the aid of an Olympus SZX10 microscope and grains from each sample were placed in individually labelled glass vials. For samples that contained both pyrrhotite and pyrite, these sulphide minerals were separated and sent as different samples to be analyzed separately. Samples were then shipped to the Stable Isotope Laboratory at the University of Maryland for sulphur isotopic analyses and these analyses are summarized below.

Samples were then transferred to flasks. A solution consisting of 20 ml of acidic Cr (II) (0.3 M) and 10 ml HCl (5 M) was added to the flasks. The reaction proceeded for three hours, during which the solution was flushed with nitrogen gas. H_2S gas was produced which passed through a water-cooled condenser, followed by a water trap (Milli-Q® water). A weakly acidic solution of $AgNO_3$ collected the silver sulfide (Ag_2S). The solution containing the silver sulphide was allowed to sit for seven days after which the silver sulphide was removed and washed with Milli-Q® water. It was then soaked in a NH_4OH solution (1 M) after which it was rinsed again using Milli-Q® water. The rinsing process was repeated ten times. For 48-72 hours, the silver sulphide was dried in an oven set to a temperature of 80°C, and then it was enfolded in aluminum foil. The silver sulphide was placed in a nickel capsule and in order to convert it to sulphur hexafluoride (SF_6), the capsule was filled with fluorine gas and heated overnight at 250°C. Purification of sulphur hexafluoride was conducted via cryogenic distillation in a mixture of liquid nitrogen (-110°C) and mixed ethanol. A gas chromatography system (molecular sieve 5A column & a 1/8 in. 4.8 m Haysep Q column, 20 ml/min flow rate) was used for additional purification. The sulphur hexafluoride was frozen using liquid nitrogen out of the helium carrier flow and subsequently relocated into a glass tube. The conversion of silver sulphide to sulphur hexafluoride had a 94-100% recovery yield. The sulphur hexafluoride was analyzed using the ThermoFinnigan MAT 253 stable isotope ratio mass spectrometer which is capable of measuring ^{36}S, ^{34}S, ^{33}S, and ^{32}S. Vienna-Canyon Diablo Troilite (V-CDT) meteorite reference standard was used to normalize the data. $\delta^{3x}S = (^{3x}S/^{32}S)_{sample}/(^{3x}S/^{32}S)_{standard}-1$ (where x=3,4,6); $\Delta^{33}S = \delta^{33}S -$

$((1+\delta^{34}S)^{0.515}-1)$; and $\Delta^{36}S = \delta^{36}S - ((1+\delta^{34}S)^{1.90}-1)$ (Canfield et al., 1986; Farquhar et al., 2007b; Wu et al., 2018; Wu, personal communication, 2018).

After every four samples, an international reference silver sulphide (IAEA-S1) was also run to quantify uncertainty. IAEA-S1 was run a total of three times during the analyses and yielded $\Delta^{33}S = 0.094 \pm 0.002‰$, $\Delta^{36}S = -0.69 \pm 0.19‰$, and $\delta^{34}S = -0.30 \pm 0.07‰$ (2 SD; n=3). Long-term variation in standard IAEA-S1 at this laboratory from 2008–2017, has yielded the following results: $\Delta^{33}S = 0.094 \pm 0.008‰$, $\Delta^{36}S = -0.69 \pm 0.30‰$, and $\delta^{34}S = -0.30 \pm 0.20‰$ which are consistent with the values of IAEA-S1 reported in this study (Wu, personal communication, 2018).

3.9 Laser ablation inductively coupled mass spectrometry (LA-ICP-MS)

To determine the age(s) of gold mineralization at the Island Gold deposit, U–Pb geochronology was performed on zircons from an intensely hydrothermally-altered dacitic sample in an ore zone and a least-altered equivalent nearby. The two samples were first crushed using a steel pestle and mortar and sieved through a 300 μm mesh. Between samples, the pestle, mortar and sieve were cleaned thoroughly by washing followed by rinsing with ethanol. Clay minerals and small, light grains were removed from the sample material that passed through the 300 μm sieve using water and a prospecting pan. After air drying each sample, a Frantz Isodynamic magnetic separator was used to remove most ferromagnesian minerals (e.g. garnet, magnetite, ilmenite) from each sample. Heavy minerals were separated by density using methylene iodide (MI) inside a fume hood. Due to the significant amount of pyrite in the hydrothermally-altered sample, it was necessary to use nitric acid to dissolve the pyrite. This sample was poured into a beaker containing a 5 molar (M) solution of nitric acid and this solution was heated on a hot plate to 80°C in a fume hood. The sample was then agitated gently until the reaction began. The reaction was allowed to proceed to completion (~45 minutes) after which the buoyant sulphur residue was removed from the surface. After the solution cooled, the mineral grains and nitric acid solution were poured through filter paper into a waste flask. During this entire process personal protective equipment was worn, lab equipment and samples were properly cleaned, waste chemicals were disposed of appropriately, and a complete procedure was followed (more detailed than the procedure summary discussed here).

Zircons were picked by hand using tweezers, with the aid of an Olympus SZX10 microscope equipped with an Olympus Highlight 3100 light source. Zircons were mounted in epoxy in 1" pucks, ground to roughly halfway through the grains, and polished to a 3 μm finish.

The pucks were covered with a conductive gold coat and zircons were imaged using a Leo 1530 Field Emission Scanning Electron Microscope equipped with a cathodoluminescence detector. Gold coating and cathodoluminescence imaging was performed by Dr. Nina Heinig at the Waterloo Advanced Technology Laboratory. Centres and rims of grains were targeted on zircons from the least-altered sample and the altered sample. Based on cathodoluminescent images and reflected and transmitted light microscopic study (Nikon Eclipse LV100POL), fractures and inclusions of other minerals within zircons were avoided.

LA-ICP-MS U-Pb geochronology was performed at the Metal Isotope Geochemistry Laboratory at the University of Waterloo. An Analyte G2 laser system with a HelEx two-volume sample cell was used in conjunction with an Agilent 8800 quadropole ICP-MS to conduct U-Pb geochronology. The elements and isotopes measured include ^{206}Pb, ^{207}Pb, ^{238}U, ^{232}Th, and ^{88}Sr. A ~25 μm in diameter spot size, fluence of 4 J/cm^2 (measured at sample surface), and a frequency of 5 Hz were used.

Zircons were ablated for 30s and aerosol was carried to the torch using ~1 L/min He with an additional ~1 L/min Ar added as a make up gas in a mixing bulb. Zircon standard DD85-17 was used as a primary standard (3002 ± 2 Ma; Tomlinson et al., 2003) and Archean standard DD91-1 (2682.4 ± 1 Ma; Davis 2002) was monitored as a secondary standard. Data was reduced using Iolite v 3.6 (Paton et al., 2011) and the U-Pb Geochronology4 data reduction scheme. No down-hole fractionation correction was applied and this, along with the different U concentrations between unknowns and standards, may explain some of the reverse discordance that is observed (Section 4.6). However, this is not expected to influence the $^{207}Pb/^{206}Pb$ ages that are considered here. The secondary standard (DD91-1) yielded a $^{207}Pb/^{206}Pb$ age of 2682 ± 6 (MSWD = 0.50), which is within the uncertainty of the accepted value. Weighted mean $^{207}Pb/^{206}Pb$ ages are reported with 95% confidence limits that include incorporation, in quadrature, of the uncertainty in the secondary reference zircons.

4.0 Results

Section 4.1 outlines the results of field, petrographic, and scanning electron microscopic study. Section 4.2 presents findings based on analysis of whole-rock geochemical data. Section 4.3 summarizes the findings from the analysis of minerals via electron microprobe. Section 4.4 presents the results pertaining to gold indicators and the distribution of gold grades within the alteration envelopes associated with auriferous quartz veining. Results pertaining to gold indicators and distribution are outlined in Section 4.4. Results of multiple sulphur isotopic analyses of sulphide minerals are presented in Section 4.5 while findings pertaining to LA-ICP-MS are outlined in Section 4.6. Figures and tables pertaining to the sections discussed above are located at the end of each of these respective sections. Major lithological units at the Island Gold deposit are referred to based on their interpreted protoliths (discussed in Section 5.1): Dacite, iron formation, gabbro, the Webb Lake stock (tonalite-trondhjemite), gabbro/lamprophyre (protolith uncertain; Section 5.1.5), quartz diorite, silica-poor diorite–monzodiorite, and diabase–quartz diabase. However, it must be noted that these units have been subject to metamorphism and are believed to be the metamorphosed equivalents of these interpreted protoliths. Mine terms used to refer to these units are included in parentheses in the header for each of these lithologies when applicable.

4.1 Field relations, petrography, and scanning electron microscopy

The results of field observations, hand sample analysis, petrography, SEM-EDS, and SEM-MLA are summarized in this chapter. First, results pertaining to vein types and gold mineralization at the Island Gold deposit are outlined in one section (Section 4.1.1). Each of the major lithologies at the Island Gold deposit then have a dedicated section where the results from these analyses are presented (Sections 4.1.2 to 4.1.9). If certain lithologies have results from both least-altered samples and samples subject to alteration related to quartz ± carbonate veining, results pertaining to least-altered and altered samples are presented in separate sub-sections. Lastly, results related to metamorphism are summarized for all lithologies in Section 4.1.10. Specific mineral names determined via electron microprobe (Section 4.3) may also be included for minerals in certain mineral groups (carbonates, chlorite, plagioclase, and white mica) and lithologies (dacite, gabbro, and the Webb Lake stock) in this section.

4.1.1 Veins and gold mineralization (V_{GD}, V_1-V_2, V_3, and V_4)

When applicable, the alteration associated with quartz veining is discussed in the corresponding alteration sub-section for each lithology (Sections 4.1.2 to 4.1.9).

4.1.1.1 Field observations

White-coloured, semi-translucent V_{GD} extensional veins are present in the Goudreau Zone as shallowly dipping, folded quartz veins (Figure 7A). These veins crosscut and alter the dacite, gabbro, and Webb Lake stock.

White-grey, translucent V_1 and V_2 veins are observed throughout the deposit. A shear that hosted V_1-V_2 veins was observed offsetting and deforming a V_{GD} vein (Jellicoe, 2019; Figure 7A). V_1-V_2 veins were observed cross-cutting and altering the dacite, Webb Lake stock, and gabbro. V_2 extensional veins are typically present as veinlets (< 1 cm across) while V_1 shear veins are often much larger. V_1 and V_2 veins are closely associated with one another in shear zones and V_1 veins often overprint V_2 veins or vice versa. In many cases, V_1 veins are a combination of subparallel V_1 shear veins and small V_2 veinlets (Figure 7B). For these reasons, it is impossible to macroscopically differentiate the effects of a V_1 versus a V_2 vein on the surrounding wall rock due to their close association. As a result, the alteration associated with these veins are studied together in this thesis. They are collectively referred to as V_1-V_2 veins.

In V_{GD}, V_1 and V_2 veins, sulphide minerals were present in greater proportions at the margins of the veins or near fragments of wall rock encompassed by the veins. These veins often contain macroscopically visible gold. Envelopes of alteration that increase in intensity moving towards these gold-bearing veins (e.g. Figure 64) are also present and are described in detail for each lithology in its corresponding section. The strength of the foliation typically increases towards these veins as well. The highest concentrations of gold are located within these veins. Gold is also present in the alteration envelopes surrounding gold-bearing quartz veins and the concentration of gold decreases moving away from these veins.

Milky-white, opaque V_3 veins were observed throughout the deposit (Figure 7C). These veins do not host gold mineralization. They are often present in shear zones associated with V_1-V_2 veining but are also situated outside of these shear zones as well. They were observed within all lithologies with the exception of the diabase–quartz diabase. These veins are often more abundant in more competent lithologies. They typically terminate within a few metres (e.g.

Figure 7B) but larger veins where terminations were not visible were also encountered in underground mine workings (e.g. Figure 7C). When these veins coincide with V_1-V_2 veins, they are often oriented perpendicular or at a high-angle to and crosscut the V_1-V_2 veins (Figure 7B). The alteration associated with V_3 veins is typically weak and is often indistinguishable. When visible, the alteration envelopes are also typically much smaller than those associated with the gold-bearing quartz veins at this deposit.

Tourmaline is typically present as semi-linear ribbons (Figure 7B; V_4 veins) or occasionally disseminated within various lithologies including V_{GD}, V_1, V_2, and V_3 quartz veins. The semi-linear tourmaline ribbons commonly parallel the trajectory of these veins (Figure 7B) as well as various other contact surfaces. These tourmaline ribbons are referred to as V_4 veins in Jellicoe (2019). Tourmaline ribbons occasionally have minor quartz and carbonate minerals associated with them as well. Tourmaline was sporadically observed within all lithologies and vein types with the exception of the diabase-quartz diabase.

4.1.1.2 Mineralogy

V_{GD}, V_1, V_2, and V_3 quartz veins are typically composed of > 90 vol% quartz whereas V_4 veins are composed mostly of tourmaline as well as occasionally minor quartz. Some carbonate minerals (calcite ± dolomite ± ankerite) are also present (typically < 10 vol%) in all vein types (Figure 8). Fragments of wall rock are often included within quartz veins and, as a result, any minerals present in the wall rock are often present in small quantities within the veins. Minor tourmaline may be present in V_{GD}, V_1, V_2, and V_3 veins but may also be completely absent.

The proportion of carbonate minerals is generally higher in V_3 veins than V_{GD}, V_1, and V_2 veins. The proportion of carbonate minerals is also slightly higher in V_2 veins than V_1 and V_{GD} veins.

Gold grains, sulphide minerals (mainly pyrite ± pyrrhotite ± chalcopyrite), chlorite, white mica, and biotite are commonly present in variable but minor quantities within V_{GD}, V_1, and V_2 veins. Actinolite is occasionally observed within V_{GD} and V_1-V_2 veins as well. Based on SEM-EDS analyses, gold grains in V_{GD}, V_1, and V_2 veins also contain minor silver (< 15 weight %). Gold was observed mainly in these auriferous quartz veins but is also present in the alteration envelopes surrounding them. Besides gold itself (which has been discussed in this section), the

other alteration minerals present in the alteration envelopes surrounding these veins are discussed in Sections 4.1.2, 4.1.4, and 4.1.5.

4.1.1.3 Textures

All quartz vein types exhibit larger quartz grains (typically 0.2-2 mm) with undulose extinction and smaller quartz grains (typically < 0.2 mm) with weaker or no undulose extinction (Figure 8A-D). Quartz grains with undulose extinction are more common in V_1 veins than V_{GD}, V_2, and V_3 veins. In some cases, these smaller, less-strained grains have sub-polygonal to polygonal boundaries. When present, sulphide and carbonate minerals tend to be concentrated along the margins of quartz veins.

Gold is typically present as free gold along mineral grain boundaries within V_{GD}, V_1, and V_2 veins in the form of μm to mm-scale droplets, layers, or veinlets (Figure 9A, B; greater than ~90% of observed gold). Occasionally gold is present as inclusions within other minerals including quartz, carbonate minerals, white mica, and pyrite (e.g. Figure 9C; less than ~10% of observed gold). In all cases, observed gold was spatially associated with sulphide minerals within a few hundred μm. Less commonly, gold grains that are texturally-equivalent to those present within veins are observed within the altered wall rock outside of V_{GD}, V_1, and V_2 veins as well. Excluding gold (which has been discussed in this section), the textures of other alteration minerals present in the alteration envelopes surrounding these veins are discussed in Sections 4.1.2, 4.1.4, and 4.1.5.

Linear tourmaline ribbons (V_4 veins) are composed of groups of tourmaline grains with their long axes oriented subparallel to one another. Blocky/massive (Figure 34A) and radial tourmaline grains (Figure 32B, D) are also occasionally present within V_4 veins or disseminated within various other lithologies as well. When present, tourmaline typically overprints other minerals it coincides with.

4.1.2 Dacitic volcanic rocks (T2, V2, I2)

4.1.2.1 Field observations

The dacitic volcanic rocks (referred to as dacite) are the most volumetrically significant protolith at the Island Gold deposit. As a result, this lithology hosts the majority of the ore zones at this deposit. These volcanic rocks are believed to be the oldest lithology within current mine

workings (Jellicoe, 2019) and are cross-cut or stratigraphically overlain by all other lithologies. At the Island Gold deposit, these rocks have been subject to greenschist-grade metamorphism and variable degrees of deformation and hydrothermal alteration. These volcanic rocks appear in a wide variety of forms including tuffs (Figure 10A-B), flows, pyroclastic breccias (Figure 10C), and hypabyssal intrusive units (Figure 10D). The tuffaceous units often contain lapilli (Figure 10B) and occasionally bomb-sized rock fragments that are mineralogically and chemically similar to the host tuff. Fragments may be composed of material equivalent to a tuff, flow, or hypabyssal intrusive.

A number of dacite-hosted alteration envelopes associated with auriferous quartz veins (V_{GD} and V_1-V_2; e.g. Figure 64A; Appendix B) at varying elevations and distances parallel to the GLDZ were sampled. Samples from within these auriferous alteration envelopes and quartz veins were subdivided into five quantitative groupings: Auriferous quartz veins, strongly-altered, moderately-altered, weakly-altered, and least-altered (Figure 12). These alteration strength groupings are discussed in detail in Section 3.2.3.

Deformation and alteration intensify towards gold-bearing quartz vein corridors. The alteration envelopes that surround these gold bearing quartz vein corridors are often approximately the same size on either side of the vein but this is not always the case. Alteration envelopes associated with V_1-V_2 veins were observed to range in size from millimetre scale up at least 10 m perpendicularly outwards from the nearest central quartz vein-wall rock contact. The central veins in the alteration envelopes studied range in size from millimetre scale to 1.5 m across. Larger gold-bearing veins were observed in underground mine workings but the extents of the alteration envelopes associated with these veins were not studied. Larger alteration envelopes are generally associated with the widest veins so alteration envelopes larger than 10 m in width are likely present. The alteration envelope associated with a V_{GD} extensional vein (~0.5 m apparent thickness) was observed to extend less than ~5 m perpendicularly outwards from the vein-wall rock contact. This is smaller than the alteration envelopes associated with V_1-V_2 shear veins of similar size. However, it is challenging to quantify the extent of alteration from a single quartz vein due to the presence of multiple quartz veins, which each have their own associated alteration envelope, within a single auriferous quartz vein corridor. Furthermore, alteration envelopes associated with neighbouring auriferous quartz vein corridors often overlap (particularly the weakly-altered portions which are the largest). In addition, continued post-

mineralization deformation has had an effect on the geometry of these alteration envelopes resulting in further variability in their shape and size. It is also difficult to quantify the size of quartz veins at the centre of alteration envelopes because these veins often pinch and swell. Occasionally no visible quartz veins are present at the centre of some alteration envelopes. Additionally, it is difficult to identify exactly where the weakly-altered outer margin of an alteration envelope ends and unaltered rock begins due to subtle differences in appearance.

A carbonate-sericite alteration zone that was not associated with quartz veining or gold mineralization was observed (Figure 13). This zone bears a resemblance to the alteration associated with auriferous zones but has a number of mineralogical and chemical differences that are discussed in the following sections. The alteration zone that was sampled and studied in this thesis was observed in drill core approximately 500 m SSW of the main Island Gold Zones. This type of alteration was not observed elsewhere during field work for this thesis. When present in the dacite, tourmaline ribbons are typically concentrated along the structural conduits such as enveloping surfaces of lithological contacts, shear zones, and quartz veins.

4.1.2.2 Least-altered samples

4.1.2.2.1 Mineralogy

The mineralogy of the dacite, in approximate order of abundance, consists of plagioclase (andesine), quartz, calcite, biotite, chlorite (ripidolite), white mica (muscovite and illite), and epidote. Accessory minerals (typically < 1 vol%) can include actinolite, apatite, chloritoid, grunerite, hematite, hornblende, ilmenite, magnetite, rutile, siderite, titanite, tourmaline, and zircon. Trace amounts of graphite were also detected by SEM-MLA but were not observed optically. In this case, the carbon coating is interpreted to have been mistaken for graphite during the automated SEM-MLA process. In a rare case, garnet was also observed in an interval of drill core composed of this lithology (Figure 65B). The volumetric proportions of minerals in a least-altered volcanic sample are displayed in Figure 11A.

4.1.2.2.2 Textures

Dacitic samples are often porphyritic and contain macroscopically-visible phenocrysts of quartz and plagioclase (< 1 cm) in an aphanitic groundmass (Figure 10A). Hypabyssal intrusive rocks are generally equigranular with a fine to medium grain size (typically <2 mm; Figure 10D).

Quartz phenocrysts observed in hand sample often have a blue colour and, based on SEM-EDS analysis, these phenocrysts have microscopic titanium-rich inclusions of rutile, titanite and/or ilmenite (discussed further in Appendix A). Plagioclase is typically anhedral–subhedral and are altered by white mica and epidote (Figure 14D). Potassium feldspar was not observed. Biotite and hornblende are usually anhedral and are partially altered or completely pseudomorphed by chlorite or actinolite. Similarly, carbonate minerals (mainly calcite) often replace hornblende and trace calcic pyroxene. Carbonates also infills irregular spaces between other mineral grains (Figure 14D) or are present as minor mm to cm-scale veinlets. Hematite alteration is occasionally associated with these calcite veinlets (Figure 10A). Actinolite, chlorite, epidote, carbonates, grunerite, hematite, ilmenite, magnetite, rutile, and titanite are intergrown with each other and often replace most other minerals (Figure 14D) excluding chloritoid, tourmaline, and garnet (when present). Chloritoid, tourmaline, and garnet overprint all other minerals. In rare cases, idioblastic to subidioblastic garnet was observed in drill core and appears to overprint all other minerals including chloritoid (Figure 65B). A timing relationship between tourmaline and garnet/chloritoid was not observed in this lithology. Chloritoid is typically randomly-oriented (Figure 65A). When present, tourmaline is typically concentrated along lithological contacts, shear planes, and the enveloping contact surfaces of veins/veinlets.

4.1.2.2.3 Primary minerals

Major primary minerals in the dacite include plagioclase (andesine), quartz, and biotite. Accessory primary minerals (typically < 1 vol%) can include apatite, hornblende, ilmenite, magnetite, and zircon. These minerals are often altered or overprinted by metamorphic minerals which are discussed cumulatively for all lithologies in Section 4.1.10.

4.1.2.3 Altered samples

4.1.2.3.1 Mineralogy

There are distinct changes in the mineral modes of variably-altered dacitic samples that have been subject to alteration related to auriferous quartz veins (Figure 16A-C). The mineral modes in Figure 16A were determined by averaging the mineral modes of dacitic samples that were classified within a specific alteration strength grouping (4 to 8 samples per group). It is challenging to differentiate between fine grained quartz and feldspar when point-counting. As a

result, these minerals are grouped together in this figure. Figure 16B is constructed based on SEM-MLA mineral proportion data from a representative dacite-hosted alteration envelope associated with a V_1-V_2 auriferous quartz vein. Quartz and feldspar can be easily differentiated using SEM-MLA analysis and their proportions are shown in Figure 16B. The mineral modes for a representative dacite-hosted alteration envelope associated with a V_{GD} auriferous quartz vein are shown in Figure 16C. Quartz and feldspars are grouped together in this figure. Averages (Table 3A) and ranges (Table 3B) of mineral proportions in dacitic samples classified under each alteration strength grouping and in quartz veins (V_1-V_2 and V_{GD}) are displayed. Point-counting and SEM-MLA mineral proportion data are located in Appendix E and Appendix F, respectively.

Alteration minerals associated with V_1-V_2 gold-bearing quartz veins in the dacites include Ca-Mg-Fe carbonates, chlorite, quartz, sulphides (pyrite ± pyrrhotite ± chalcopyrite), white mica (muscovite), and trace amounts of rutile. The proportion of quartz steadily decreases while plagioclase modes increase when moving away from auriferous quartz veins towards least-altered material (Figure 16B). Strongly-altered dacite is dominated by white mica and pyrite but also has substantial amounts of carbonate minerals (Figure 16A, B). Trace amounts of chalcopyrite, closely associated with pyrite, are often present in this zone as well. In the moderate zone, the proportion of carbonate minerals increases while pyrite content decreases dramatically, and chlorite modes increase while white mica modes decrease (Figure 16A, B). Minor pyrrhotite often appears in the moderate zone as well (Figure 16A). The weak zone is characterised by substantial decreases in the amount of white mica, carbonates and sulphides and chlorite modes continue to increase (Figure 16A, B). Least-altered dacitic samples are characterized by the absence of pyrite and a decrease in the amount of chlorite relative to the weak zone (Figure 16 31A, B). Trace disseminated magnetite is often present in the weakly-altered and least-altered samples of the dacite. Trace potassium feldspar was identified via SEM-MLA in samples altered by V_1-V_2 veins (Figure 16B) but is present in insignificant proportions and was not verified optically. The mineralogy of least-altered samples is discussed in Section 4.1.2.2.1. A V_2 veinlet was encountered in a dacitic sample weakly to moderately-altered by larger V_1-V_2 veins nearby. A thin section that includes this V_2 veinlet and an associated cm-scale alteration envelope was analyzed by SEM-MLA. An SEM-MLA image of this thin section using false colours for minerals and displaying approximate boundaries between alteration zones is shown in Figure 18. Based on visual estimates, the alteration mineral assemblage and mineral

proportions are equivalent to the alteration associated with V_1-V_2 combination veining on a larger scale. Photomicrographs of dacitic samples variably-altered by V_{GD} and V_1-V_2 veining are displayed in Figure 67 (Appendix B) and Figure 14, respectively.

Overall, the alteration mineral assemblage associated with V_{GD} veins located in the Goudreau Zone is consistent with the alteration associated with V_1-V_2 veins. However, there is a larger proportion of white mica and chlorite and a smaller amount of quartzofeldspathics minerals than typically observed in alteration envelopes associated with V_1-V_2 veins (Figure 16). In addition, the largest concentration of carbonate minerals in alteration envelopes associated with V_{GD} veins is typically in strongly-altered samples (Figure 16C) rather than in moderately-altered samples (Figure 16A, B). Furthermore, weakly-altered samples from the Goudreau Zone also have more white mica and chlorite than typically observed in weakly-altered samples associated with V_1-V_2 veins elsewhere in the deposit (Figure 16).

A number of ore zones were sampled throughout the deposit and the locations of these ore zones relative to mine workings are displayed in Figure 19. Figures displaying the volumetric changes in mineralogy moving away from the centre of each of these zones are displayed in Figure 68 (Appendix B). Based on these results, alteration mineral assemblages associated with auriferous quartz veins are generally consistent along strike and at various depths within the deposit. However, there are a few notable variations in the proportions of these minerals between zones. The volumetric percentage of quartz in the strongly-altered sample from the deep zone associated with V_1-V_2 veins (~1300 m depth) has more quartz and feldspar (64 vol%) when compared to the average quartzofeldspathic mineral content of all strongly-altered samples (46 vol%). Based on petrographic study, it is clear that this increase in quartzofeldspathic minerals can be attributed to silicification of this sample.

In addition, the strongly-altered sample from a V_1-V_2 ore zone located approximately at the centre of current mine workings (~500 m depth) has more white mica (44 vol%) when compared to the white mica content in the average strongly-altered sample (33 vol%).

Furthermore, carbonate content is very low in the strongly-altered samples in both the central (< 1 vol%) and deep ore zones (~1 vol%) associated with V_1-V_2 veins. However, carbonate content is commonly low in very strongly-altered samples directly proximal to auriferous quartz veins. These samples often contain small quartz veinlets and silicification rather than substantial carbonation. Moderately-altered samples associated with V_1-V_2 veins are

typically composed of a substantial amount of carbonate minerals, but this was not verified petrographically in the central and deep ore zones.

An altered zone that was not associated with quartz veining or gold mineralization was also encountered. The mineralogy of this alteration is similar to the strongly-altered material associated with auriferous quartz veins but can be differentiated based on the lack of both sulphides and quartz veining/silicification. These zones are characterized by strong sericitization and the presence of substantial interstitial carbonates and carbonate veinlets.

4.1.2.3.2 Textures

V_1-V_2 alteration-derived quartz, white mica (muscovite), sulphides, carbonates, rutile, and chlorite commonly overprint or alter primary and pre-existing metamorphic minerals present in the least-altered dacitic samples (which mainly consist of plagioclase, quartz, calcite, chlorite, biotite, and epidote; Figure 14A-C). When present, tourmaline overprints all minerals. In strongly-altered samples microscopic quartz veinlets may be present. Both chlorite and white mica commonly alter biotite and other minor ferromagnesian minerals (Figure 14A-C). Alteration-derived chlorite is intergrown with other alteration minerals. White mica commonly replaces chlorite (Figure 14B, C). Pyrite is the dominant sulphide mineral and is typically spatially associated with ferromagnesian minerals. When present, pyrrhotite and chalcopyrite are closely associated with pyrite. Ca-Mg-Fe carbonates are present as variably-shaped masses between other grains. Rutile typically replaces ilmenite and titanite. Many primary textures such as quartz and feldspar phenocrysts are no longer visible in moderately or strongly-altered samples (Figure 14). The strongly-altered samples typically have a stronger foliation (Figure 14A) and are often finer-grained than least-altered samples (Figure 14D). Furthermore, these strongly-altered samples often contain elongate minerals with preferential orientations (Figure 14A). The alteration minerals and textures discussed above are also observed in samples altered by V_{GD} veins (Figure 67; Appendix B). Samples altered by V_1-V_2 shear veins (Figure 12A) are typically more deformed than those in samples altered by V_{GD} extensional veins (Figure 66A; Appendix B).

Besides the notable absence of quartz veining/silicification and pyrite, samples from the non-auriferous, sericite-carbonate alteration zones are texturally similar to samples from

alteration zones associated with auriferous veining (Figure 15). Similar to many V_1-V_2 and V_{GD} vein-related alteration zones, tourmaline was also observed within these samples (Figure 13).

4.1.2.3.3 Carbonate-sericite, V_{GD}, and V_1-V_2-vein related alteration minerals

V_{GD} vein-related alteration and V_1-V_2 vein-related alteration of dacite both result in the same alteration mineral assemblage which replaces primary and pre-existing metamorphic minerals. These alteration minerals include Ca-Mg-Fe carbonate minerals, chlorite (ripidolite), quartz, sulphides (pyrite ± pyrrhotite ± chalcopyrite), and white mica (muscovite). Non-auriferous carbonate-sericite alteration minerals mainly include carbonate minerals and white mica which also commonly replace primary and pre-existing metamorphic minerals (Figure 15).

4.1.3 Iron formation (IF)

4.1.3.1 Field observations

Iron formations separate the dacitic rocks from the mafic volcanic rocks to the north. In rare cases, iron formations are occasionally interbedded with dacitic rocks in drill core. Cross-cutting relationships between this lithology and intrusive lithologies at the Island Gold deposit were not observed. Massive sulphide and iron oxide-rich iron formations with no macroscopically visible layering (Figure 21A, C) and banded iron formations are present (Figure 21B). When visible, layers appear to be composed of iron oxides and sulphides alternating with chert, carbonate, and chlorite-rich layers. In one outcrop, the iron formation contains large dacite clasts stretched parallel to the foliation (Figure 21D).

4.1.3.2 Mineralogy

The mineralogy of the sulphide and iron oxide-rich layers of the iron formation consist of mainly hematite, magnetite, and pyrite. The proportions of minerals vary considerably within this layer grouping with layers ranging from mostly iron oxides (Figure 22A) to mainly sulphides (Figure 22B, D). Iron oxide and sulphide-rich layers are separated by layers with various proportions of quartz, carbonate minerals, chlorite, and plagioclase. Some layers are mainly composed of quartz (Figure 22C), others are dominantly composed of chlorite and biotite (Figure 22C), and others mostly consist of carbonate minerals (Figure 22D). Accessory minerals can

include chloritoid, epidote, ilmenite, white mica, and tourmaline. The heterogeneous and layered nature of this unit makes point-counting analyses unsuitable.

4.1.3.3 Textures

Iron oxide and sulphide-rich layers in the iron formation range from fine to coarse-grained whereas silicate-rich layers are typically fine grained. Iron oxides and sulphide minerals are present as massive bands (Figure 22A, B, D). Carbonates are interstitial or are present as minor mm to cm-scale carbonate veinlets. Hematite alteration is occasionally associated with these carbonate veinlets. Plagioclase feldspar is anhedral and is typically altered by chlorite, epidote, carbonates, and white mica. Biotite is often replaced or pseudomorphed by chlorite but, in some cases, biotite appears to overprint chlorite (Figure 22C). Carbonates, chlorite, epidote, ilmenite, and white mica commonly replace or overprint most other minerals with the exception of chloritoid and tourmaline. When present, tourmaline and randomly oriented chloritoid grains overprint all minerals. A timing relationship between chloritoid and tourmaline was not observed in this lithology.

4.1.3.3.1 Primary minerals

Major primary minerals in the banded to massive iron formations include carbonate minerals, hematite, magnetite, plagioclase, pyrite, and quartz. Proportions of minerals vary considerably depending on the layer being observed. Primary clay minerals were not observed but may have been the precursors of the chlorite and biotite-rich layers prior to metamorphism.

4.1.4 Gabbro (I3G)

4.1.4.1 Field observations

Gabbro is common at the Island Gold deposit and is present as sills and dykes that cross-cut the dacitic rocks. These rocks have been subject to metamorphism and variable degrees of deformation and hydrothermal alteration. This lithology is distinguished based on its deep green colour due to significant chlorite content (Figure 23D). This lithology hosts a small proportion of the ore at the Island Gold deposit (< 10%). A gabbro-hosted alteration envelope associated with V_1-V_2 auriferous veining was sampled (Figure 23). Samples from this alteration envelope and other samples of this lithology were taken throughout the deposit and were subdivided into five

quantitative groupings: Auriferous quartz veins, strongly-altered, moderately-altered, weakly-altered, and least-altered (Figure 23; Section 3.2.3). This gabbro also hosted V_{GD} veins in the Goudreau Zone. However, both V_{GD} and V_1-V_2 veining were present in this location so it was impossible to discern the effects of V_{GD} veining alone on this lithology. As a result of this, the effects of V_{GD} veins on this lithology were not studied.

Similar to ore zones hosted by other lithologies, deformation and alteration intensify towards gold-bearing quartz veining (Figure 23) and alteration envelopes observed were approximately the same width on either side of the vein. The auriferous quartz vein at the centre of the alteration envelope sampled consists of a small group of veins/veinlets each of which are less than 0.1 m across. The total extent of this alteration envelope hosted by this lithology could not be determined because a contact with dacite was encountered ~2.4 m up-hole from the auriferous veins (~1.4 m perpendicular distance from the vein-wall rock contact) while still in a weakly-altered zone of the alteration envelope. However, the start of the moderately-altered zone appears to be approximately the same perpendicular distance from the vein contact as in a dacite-hosted zone associated with a quartz vein of similar size (~1.9 m versus ~2.2 m, respectively). The challenges summarized in Section 4.1.2.1 regarding the quantification of quartz vein and alteration envelope sizes/extents were also encountered when studying this gabbro-hosted ore zone.

4.1.4.2 Least-altered samples

4.1.4.2.1 Mineralogy

The mineralogy of the gabbro, in approximate order of abundance, consists of chlorite (ripidolite), quartz, epidote, carbonates (mainly calcite), actinolite, titanite, plagioclase (oligoclase–andesine), and hornblende. Accessory minerals can include chloritoid, hematite, ilmenite, magnetite, clinopyroxene, rutile, tourmaline, and white mica (phengite). The proportions of minerals in a representative least-altered sample of gabbro are displayed in Figure 11B. The compositions of select minerals were determined by microprobe (Section 3.6). In one case, garnet was also observed in a hand sample.

4.1.4.2.2 Textures

Least-altered samples of the gabbro (Figure 23D; Figure 24D) are typically equigranular and medium-grained (1-3 mm). Carbonate minerals are interstitial (Figure 24D) or are present as mm to cm-scale carbonate veinlets (Figure 23D). Hematite alteration is occasionally associated with these calcite veinlets. Plagioclase is anhedral and is typically replaced by chlorite, epidote, calcite, and white mica (Figure 24D). Potassium feldspar was not observed. Hornblende and pyroxene are often pseudomorphed by actinolite, chlorite, and calcite. Actinolite, calcite, chlorite, epidote, ilmenite, quartz, rutile, titanite, and white mica are often intergrown and commonly overprint most other minerals (Figure 24D) excluding chloritoid, tourmaline, and garnet (when present). Chloritoid, tourmaline, and garnet overprint all other minerals. Idioblastic garnet was only observed in one hand sample and appears to overprint all other minerals including chloritoid. A timing relationship between tourmaline and garnet/chloritoid was not observed.

4.1.4.2.3 Primary minerals

In the majority of the least-altered gabbroic samples, the breakdown and replacement of primary plagioclase and ferromagnesian minerals due to metamorphism is fairly pervasive. As a result, the proportion of primary minerals is low relative to most other lithologies. When present, major primary minerals consist of plagioclase, clinopyroxene, and hornblende. Accessory primary minerals can include ilmenite, magnetite, and quartz.

Due to the low proportions of primary minerals, it is not appropriate to classify this lithology by point-counting to determine mineral modes and plotting on conventional mineralogical classification plots such as the Quartz-Alkali Feldspar-Plagioclase (QAP) ternary diagram. Instead, geochemistry is used in Section 4.2.4.1 to suggest a likely classification.

4.1.4.3 Altered samples

4.1.4.3.1 Mineralogy

Figure 17A illustrates the volumetric changes in the mineralogy of the gabbro with varying intensities of alteration. It is challenging to accurately differentiate between fine grained quartz and feldspar so these minerals are grouped together in this figure. However, based on petrographic estimates, quartz content decreases while plagioclase content increases with

increasing alteration. However, quartz content is typically higher immediately proximal to V_1-V_2 veins/veinlets. Alteration minerals associated with this auriferous corridor include biotite, calcite, chlorite (ripidolite), plagioclase (oligoclase), quartz, rutile, white mica (phengite), and sulphides (pyrite ± pyrrhotite ± chalcopyrite). The strongly-altered sample contains significant biotite, calcite, and pyrite (Figure 17A). In the moderate zone, the amount of carbonate minerals decreases slightly, pyrite content decreases substantially, the amount of biotite decreases, and chlorite content decreases relative to the strong zone (Figure 17A). Minor pyrrhotite is often present in the moderate zone as well. Relative to the moderate zone, the weak zone is characterized by substantial decreases in biotite, calcite, and sulphides and chlorite content increases (Figure 17A). Least-altered samples are characterized by a decrease in biotite, calcite, chlorite, and white mica relative to weakly-altered samples. There is also an increase in the proportions of actinolite, epidote, hornblende, and titanite relative to altered samples (Figure 17A).

4.1.4.3.2 Textures

Alteration-derived biotite, calcite, chlorite, plagioclase (oligoclase), quartz, rutile, white mica (phengite), and sulphides commonly replace primary and pre-existing metamorphic minerals that are present in the least-altered samples of gabbro (Figure 24A–C). When present, tourmaline overprints all minerals. In altered samples, microscopic quartz veinlets may be present. Quartz content increases directly adjacent to veins/veinlets, but away from these veinlets, quartz is replaced by plagioclase. Biotite frequently replaces chlorite (Figure 24A–C) and primary ferromagnesian minerals. Alteration-derived chlorite is intergrown with other alteration-derived minerals (Figure 24A–C). When present, white mica replaces feldspar and chlorite grains. Rutile replaces ilmenite and titanite. Pyrite is the dominant sulphide mineral and is typically spatially associated with other ferromagnesian minerals (Figure 24A-C). When present, pyrrhotite and chalcopyrite are spatially associated with pyrite. Interstitial calcite is present as variably shaped masses. Primary and metamorphic minerals such as pyroxene, hornblende, and actinolite were not observed in moderately or strongly-altered samples. The strongly-altered samples (Figure 24A) typically have a stronger foliation than less-altered samples (Figure 24D). These strongly-altered samples have more elongated and preferentially oriented minerals compared to less-altered samples (Figure 24).

4.1.4.3.3 V_1-V_2 vein-related alteration minerals

Minerals that form in the gabbro as a result of V_1-V_2 veining include biotite, calcite, chlorite (ripidolite), plagioclase (oligoclase), quartz, rutile, sulphides (pyrite ± pyrrhotite ± chalcopyrite) and, occasionally, minor white mica and these minerals commonly replace primary and pre-existing metamorphic minerals.

4.1.5 Webb Lake stock: Tonalite–trondhjemite (I1JM)

4.1.5.1 Field observations

The Webb Lake stock is a relatively minor lithology at the Island Gold deposit but does host economic gold grades if it is located adjacent to an auriferous quartz vein. However, the Webb Lake stock hosts the majority of the ore at the Magino deposit to the west of the Island Gold deposit (Turcotte and Pelletier, 2008; Figure 4). The competency contrast between this intrusive body and the volcanic rocks that surround it is interpreted to have concentrated strain resulting in the emplacement of the auriferous veins at the Island Gold deposit (Jellicoe, 2019). The Webb Lake stock cross-cuts both the dacite and gabbro. The Webb Lake stock has been subject to metamorphism and variable intensities of deformation and hydrothermal alteration. The samples studied in this thesis were taken from the outer margins of this Webb Lake intrusion. Based on visual estimates, samples closer to the periphery of the intrusion (Figure 25A) have more ferromagnesian minerals than those nearer to the centre (Figure 25C). Tourmaline veining occasionally invades the foliation and earlier quartz veining within this lithology (Figure 25B).

An alteration envelope associated with a V_1-V_2 auriferous vein and hosted by this lithology at the Island Gold deposit was sampled (Figure 26). The Webb Lake stock also hosted V_{GD} veins in areas near the Goudreau Zone but these areas were inaccessible during site visits. As a result, the effect of V_{GD} veins on this lithology was not studied. Samples from this alteration envelope and other samples of this lithology were taken throughout the deposit and were subdivided into five quantitative groupings: Auriferous quartz veins, strongly-altered, moderately-altered, weakly-altered, and least-altered (Figure 26; Section 3.2.3). Similar to ore zones hosted by other lithologies, deformation and alteration intensify towards the gold-bearing quartz vein. The auriferous quartz vein at the centre of the alteration envelope is approximately 0.6 m across. The outer boundary of the alteration envelope is relatively sharp and easier to

identify than the outer boundaries of alteration envelopes hosted by dacite or gabbro. The perpendicular distance between the upper vein-wall rock contact and least-altered material was approximately 1.6 m. The perpendicular distance between the lower vein-wall rock contact and least-altered material was approximately 4.0 m. This alteration envelope is asymmetrical although other Webb Lake stock-hosted alteration envelopes were approximately symmetrical. Both ~1.6 m and ~4.0 m extents are appreciably smaller than those from alteration envelopes associated with V_1-V_2 veins and hosted by dacite or gabbro. The challenges discussed in Section 4.1.2.1 regarding the quantification of quartz vein and alteration envelope sizes/extents were also encountered when studying Webb Lake stock-hosted ore zones.

4.1.5.2 Least-altered and weakly-altered samples

4.1.5.2.1 Mineralogy

The mineralogy of the least-altered sample of the Webb Lake stock (Figure 25A; Figure 28D) in order of abundance is as follows: Plagioclase (albite–oligoclase), quartz, chlorite (ripidolite), biotite, white mica (phengite ± muscovite), epidote, and calcite. Accessory minerals can include actinolite, apatite, chloritoid, hematite, hornblende, ilmenite, pyrite, pyroxene, rutile, titanite, tourmaline, and zircon. The proportions of minerals in a least-altered sample of the Webb Lake stock are displayed in Figure 11C. The proportions of ferromagnesian minerals in point-counted samples classified as weakly and least-altered range from 9–20 vol%. These samples were taken from the outer margins of this Webb Lake intrusion. Based on visual estimates, samples away from the margins of the intrusion had fewer ferromagnesian minerals.

4.1.5.2.2 Textures

The Webb Lake stock (Figure 25A; Figure 28D) is equigranular with a medium to coarse grain size (1–8 mm). Similar to quartz in the dacite, quartz often has a blue colour and phenocrysts have microscopic titanium-rich inclusions of rutile and/or ilmenite. Calcite is interstitial (Figure 28D) or present as carbonate veinlets that are millimetres to centimetres in width. Hematite alteration is occasionally associated with these calcite veinlets. Feldspars are subhedral to euhedral and are typically altered by fine grained epidote, white mica, and calcite (Figure 28D). Trace hornblende and pyroxene are often pseudomorphed by actinolite, chlorite, and calcite. Biotite is partially or completely replaced by chlorite (Figure 28D). When present

actinolite, calcite, chlorite, epidote, ilmenite, rutile, and titanite are intergrown and often overprint most other minerals excluding chloritoid and tourmaline which are occasionally present in this lithology. Chloritoid and tourmaline overprint all other minerals. A timing relationship between tourmaline and chloritoid was not observed.

4.1.5.2.3 Primary minerals

Major primary minerals in the Webb Lake stock, in approximate order of abundance, include plagioclase (albite–oligoclase), quartz, and biotite. Accessory primary minerals include apatite, hornblende, ilmenite, pyroxene, and zircon.

Based on mineral modes determined via petrographic point counting techniques, three samples of this lithology plot in the tonalite field of a QAP diagram (Figure 27). Difficulty accurately distinguishing between plagioclase compositions petrographically makes point-counting techniques inappropriate for plotting on the Anorthite-Albite-Orthoclase ternary diagram. As a result, geochemistry and CIPW Normative calculations are used to determine the modal proportions of these feldspar end-members for this ternary diagram (Section 4.2.5.1).

4.1.5.3 Altered samples

4.1.5.3.1 Mineralogy

Figure 17B highlights the changes in mineral proportions in the Webb Lake stock with varying intensities of alteration related to V_1-V_2 veining. The alteration assemblage present in this alteration envelope includes biotite, Ca-Mg-Fe carbonates, quartz, rutile, sulphides (pyrite ± pyrrhotite ± chalcopyrite), and white mica (muscovite/phengite). Plagioclase content steadily increases while quartz content generally decreases moving from the V_1-V_2 auriferous veins to least-altered material (Figure 17B). The strong alteration zone of the Webb Lake stock contains significant proportions of white mica, carbonate minerals, and pyrite (Figure 17B). In the moderate zone, biotite content increases significantly while pyrite and carbonate content decrease relative to the strong zone. Some chlorite is also present in the moderate zone (Figure 17B). Minor pyrrhotite and chalcopyrite closely associated with pyrite are generally restricted to auriferous quartz veins in addition to strongly and moderately-altered samples. Sulphide minerals are typically only present in trace amounts beyond the moderate zone (Figure 17B). The weak zone is characterized by a decrease in the amount of white mica, biotite, and carbonates as well

as an increase in the amount of chlorite relative to the moderate zone (Figure 17B). In least-altered samples, white mica content decreases while the proportions of epidote and chlorite increase (Figure 17B). The mineralogy of the least-altered samples is discussed in Section 4.1.5.2.

4.1.5.3.2 Textures

Alteration-derived biotite, Ca-Mg-Fe carbonates, quartz, white mica (muscovite/phengite), and sulphides (pyrite ± pyrrhotite ± chalcopyrite) commonly overprint and/or alter the primary and pre-existing metamorphic minerals present in the least-altered samples of the Webb Lake stock (mainly plagioclase, quartz, calcite, chlorite, biotite, and epidote). When present, tourmaline overprints all minerals it coincides with. In altered samples, quartz is present as subhedral grains as well as interstitial anhedral grains (Figure 28A). In strongly-altered samples microscopic quartz veinlets are occasionally present. White mica often replaces chlorite grains and feldspars. Rutile commonly replaces ilmenite and titanite. Biotite frequently alters chlorite in moderately and strongly altered samples (Figure 28A, B). Pyrite is the dominant sulphide mineral and typically concentrates near ferromagnesian minerals (Figure 28A). When present, pyrrhotite and chalcopyrite are closely associated with pyrite. Ca-Mg-Fe carbonates are present as interstitial masses or replace primary and pre-existing metamorphic Ca-bearing minerals (Figure 28). The strongly-altered samples typically have a stronger foliation and are often finer-grained than less-altered samples (Figure 28).

4.1.5.3.3 V_1-V_2 vein-related alteration minerals

Alteration of the Webb Lake stock as a result of V_1-V_2 veining resulted in the growth of biotite, Ca-Mg-Fe carbonates, chlorite (ripidolite), quartz, rutile, sulphides (pyrite ± pyrrhotite ± chalcopyrite), and white mica (muscovite ± phengite) at the expense of primary and pre-existing metamorphic minerals.

4.1.6 Gabbro/Lamprophyre (I2H)

4.1.6.1 Field observations

The gabbro/lamprophyre (Figure 29A; protolith uncertain; likely gabbro or lamprophyre; discussed in Section 5.1.5) occurs as sills and dykes that have been metamorphosed and

deformed. In many cases, it is challenging to distinguish between the gabbro, silica-poor diorite–monzodiorite, and gabbro/lamprophyre macroscopically. Intrusions of the gabbro/lamprophyre cross-cut the dacite and gabbro. Dacitic xenoliths are occasionally present within intrusions of the gabbro/lamprophyre (Figure 29B). The gabbro/lamprophyre, Webb Lake stock, and the quartz diorite were not observed in the same area so a definitive timing relationship could not be determined. However, V_1-V_2 veins do crosscut the Webb Lake stock while these veins were not observed crosscutting the gabbro/lamprophyre.

The gabbro/lamprophyre is commonly oriented parallel to gold-bearing quartz vein corridors associated with V_1-V_2 auriferous veins. As a result, clear, high-angle cross-cutting relationships between auriferous veins and this lithology are rarely observed. However, despite being located directly adjacent to V_1-V_2 quartz veins with visible gold, this lithology typically does not exhibit the typical alteration features that gold-hosting lithologies (dacite, gabbro, and the Webb Lake stock) commonly exhibit when near V_1-V_2 veins. In addition, despite the contact between gabbro/lamprophyre and auriferous quartz veins being parallel to the approximate strike of both, these auriferous quartz veins abruptly end at the contact with this lithology indicating that gabbro/lamprophyre cross-cuts these veins and their associated alteration envelopes. Based on the presence of a strong foliation in this lithology, particularly when present in gold-bearing quartz vein corridors, it is evident that this lithology has been subject to deformation after emplacement (Figure 29A). V_3 non-auriferous quartz veins cross-cut, alter (Figure 29C), and occasionally brecciate this intrusion (Figure 29D). Occasionally, slightly larger and more intense alteration aureoles (< 0.2 m away from the quartz vein-gabbro contact) are present in this lithology when it is located directly adjacent to V_1-V_2 veining with intermixed V_3 veins (e.g. Figure 30). This stronger alteration is not present when this lithology is located adjacent to V_1-V_2 veins that are not associated with any visible V_3 veining. Tourmaline may be present or absent in these V_3 veins. When present in the gabbro/lamprophyre, tourmaline veins/ribbons are often concentrated at the contact between gabbro/lamprophyre and neighbouring lithologies (e.g. Figure 30).

4.1.6.2 Least-altered samples

4.1.6.2.1 Mineralogy

The mineralogy of the gabbro/lamprophyre (Figure 29A; Figure 31), in approximate order of abundance, consists of quartz, oligoclase–andesine, carbonate minerals, chlorite, and white mica. Accessory minerals can include actinolite, epidote, hematite, rutile, titanite, tourmaline, and zircon. The proportions of minerals in a representative least-altered sample of gabbro/lamprophyre are displayed in Figure 11D. It is challenging to accurately differentiate between fine-grained quartz and feldspar so they are grouped together in this figure. However, based on visual estimates, there is a larger proportion of quartz than plagioclase in this lithology.

4.1.6.2.2 Textures

The gabbro/lamprophyre is typically equigranular with mainly a fine to medium grain size (<5 mm; Figure 31B). Carbonate minerals are present as subhedral grains, interstitial anhedral grains (Figure 31B), or minor mm- to cm-scale carbonate veinlets. Hematite alteration is occasionally associated with these carbonate veinlets. Plagioclase feldspars are anhedral and are typically replaced by chlorite, epidote, carbonates, and white mica (Figure 31B). Potassium feldspar was not observed. Actinolite, carbonates, chlorite, epidote, quartz, titanite, rutile, and white mica are intergrown and often replace most other minerals excluding tourmaline (Figure 31B). When present, tourmaline overprints all minerals and is typically concentrated along microstructural conduits such as shear planes and veinlets.

4.1.6.2.3 Primary minerals

The breakdown and replacement of primary plagioclase and ferromagnesian minerals is pervasive in all samples of the gabbro/lamprophyre. Trace primary zircon was also optically identified. Based on the chemical composition (Section 4.2.6) and the metamorphic mineral assemblage (Section 4.1.10), likely primary minerals are discussed in Section 5.1.5.

Due to the low proportions of primary minerals, it is not appropriate to classify this lithology by point-counting to determine mineral modes and subsequently use this data to plot on conventional mineralogical classification plots such as the Quartz-Alkali Feldspar-Plagioclase (QAP) ternary diagram. Instead, geochemistry is used in Section 4.2.6.1 to suggest a likely classification.

4.1.6.3 Altered samples

4.1.6.3.1 Mineralogy

The mineralogy of a sample of the gabbro/lamprophyre altered by a proximal V_3 vein consists mainly of quartz, plagioclase, carbonate minerals, chlorite, and white mica. Based on visual petrographic estimates, this sample (T213), which has been altered by a non-auriferous V_3 vein, has notable increases in the amount of white mica (± minor fuchsite) compared to least-altered samples. In addition, epidote content decreases relative to least-altered samples and only trace amounts are present in the altered sample. Chlorite content decreases but this mineral still makes up a large proportion of the sample. Proportions of other minerals, including sulphides, remain similar to the proportions in least-altered samples.

4.1.6.3.2 Textures

White mica and large carbonate grains commonly replace the minerals in the least-altered samples of the gabbro/lamprophyre (Figure 31A), with the exception of tourmaline (when present). White mica grains are often randomly oriented and the long axes of these minerals are often not parallel to the dominant foliation (Figure 31A). On average, carbonate mineral grains in altered samples are larger than those in least-altered samples (Figure 31). Carbonates are interstitial or are present as subhedral–euhedral grains (Figure 31A). Plagioclase feldspars are anhedral and are altered by chlorite, epidote, carbonates, and white mica. This altered sample has an overall coarser-grain size than most least-altered samples (Figure 31).

4.1.6.3.3 V_3-vein related alteration minerals

The minerals that form in gabbro/lamprophyre as a result of V_3 vein-related alteration and replace primary and pre-existing metamorphic minerals are mainly white mica (± fuchsite) and carbonates.

4.1.7 Quartz diorite

4.1.7.1 Field observations

Xenoliths of the red/pink-coloured quartz diorite were identified within an intrusion of silica-poor diorite–monzodiorite on the 620 level (Figure 32A). These xenoliths contain visible carbonate (± quartz ± tourmaline) veinlets and have been subject to metamorphism and

deformation. This quartz diorite also occurs on the 600 level in the form of a dyke cross-cutting the dacite but the location of this occurrence on this level was not accessible. This intrusion was not encountered elsewhere in mine workings and was not encountered proximal to auriferous quartz veining.

4.1.7.2 Mineralogy

The mineralogy of a quartz diorite sample (T215; Figure 32B–D), in approximate order of abundance, consists of plagioclase (albite), quartz, carbonate minerals, hematite, and chlorite. Accessory minerals include biotite, epidote, magnetite, titanite, tourmaline, white mica, and zircon. Despite the pink colouration of this intrusive lithology, potassium feldspar is absent and plagioclase makes up the majority of this intrusion. There is also a substantial amount of hematite. The proportions of minerals in a representative quartz diorite sample are displayed in Figure 11E.

4.1.7.3 Textures

The quartz diorite is generally equigranular with typically a medium grain size (1–5 mm; Figure 32C, D). Carbonate minerals are interstitial (Figure 32D) or present as parallel mm to cm-scale carbonate veinlets (Figure 32A, B). Microscopic hematite inclusions (< 10 μm) are present along fracture surfaces or as inclusions within plagioclase grains (Figure 32C). In addition, larger anhedral–euhedral magnetite and hematite grains are also present. Plagioclase feldspars are typically subhedral–euhedral and are weakly-altered by chlorite, epidote, carbonates, and white mica (Figure 32D). Trace amounts of biotite are replaced or pseudomorphed by chlorite. Carbonates, chlorite, epidote, hematite, magnetite, quartz, titanite, and white mica are intergrown and replace most other minerals (Figure 32C, D) excluding tourmaline. Tourmaline typically overprints all minerals and is concentrated along microstructural conduits such as quartz-carbonate veinlets and grain boundaries (Figure 32B).

4.1.7.4 Primary minerals

Major primary minerals in the quartz diorite, in approximate order of abundance, include plagioclase (albite) and quartz. Accessory primary minerals can include biotite, magnetite, and

zircon. Based on mineral modes determined via petrographic point counting techniques, this lithology plots in the quartz diorite field of the QAP diagram (Figure 27).

4.1.8 Silica-poor diorite–monzodiorite (I2M)

4.1.8.1 Field observations

Silica-poor dioritic–monzodioritic intrusions are commonly present as sills and dykes that have been subject to metamorphism and deformation. These diorite–monzodiorite intrusions cross-cut the dacite and gabbro. A sharp contact between the silica-poor diorite–monzodiorite and the gabbro/lamprophyre was observed in drill core (Figure 33C) but the cross-cutting relationship is unclear. In a few cases within underground workings, the silica-poor diorite–monzodiorite appears to cross-cut the gabbro/lamprophyre. However, due to difficulty differentiating between the gabbro/lamprophyre and silica-poor diorite–monzodiorite in this setting, these cross-cutting relationships are ambiguous. Additionally, both of these lithologies are relatively minor and commonly parallel each other within mine workings so clear, high-angle, cross-cutting relationships were not observed. The silica-poor diorite–monzodiorite is notably less deformed than the gabbro and gabbro/lamprophyre when these lithologies are located in the same area and compared.

Large, volumetrically significant and partially resorbed xenoliths of quartz diorite were observed within this intrusive lithology as well (Figure 32A). Silica-poor dioritic–monzodioritic samples may be grey-coloured (Figure 33A) or have a slight pink–red colouration (Figure 33B) which is a less intense variety of the distinct pink–red colour of the hematite-rich quartz diorite lithology. Particularly when present in gold-bearing quartz vein corridors, it is evident that this lithology has been subject to some deformation after emplacement. The silica-poor diorite–monzodiorite and the Webb Lake stock were not observed to occur in the same area so a definitive timing relationship could not be determined. However, V_1-V_2 veins crosscut the Webb Lake stock while these veins were not observed crosscutting the silica-poor diorite–monzodiorite despite the silica-poor diorite–monzodiorite commonly paralleling V_1-V_2 auriferous veins. As a result, clear, high-angle cross-cutting relationships between auriferous veins and this lithology are rarely observed. However, despite being located directly adjacent to V_1-V_2 quartz veins with visible gold, this lithology does not exhibit the alteration features that gold-hosting lithologies (dacite, gabbro, and the Webb Lake stock) commonly exhibit when near V_1-V_2 veins. In

addition, despite the contacts between the silica-poor diorite–monzodiorite and auriferous quartz veins typically being parallel to their approximate strikes, these auriferous quartz veins abruptly end at the contact with this lithology indicating that the silica-poor diorite–monzodiorite cross-cuts these veins and their associated alteration envelopes (Figure 34C). In many cases, small alteration aureoles (10 cm perpendicular distance from the quartz vein-diorite–monzodiorite contact) are present in this lithology when it is directly adjacent to V_3 veins or V_1-V_2 veins with intermixed V_3 veins (Figure 34A). This alteration is typically not present when this lithology is located adjacent to V_1-V_2 veins that are not associated with any visible V_3 veining (e.g. Figure 34C). Tourmaline may be present or absent from these V_3 veins. When present, tourmaline veins/ribbons are often concentrated at the contact between the silica-poor diorite–monzodiorite and the host-rock that it intrudes.

4.1.8.2 Least-altered samples

4.1.8.2.1 Mineralogy

The mineralogy of the silica-poor diorite–monzodiorite, in approximate order of abundance, consists of plagioclase (oligoclase), carbonate minerals, biotite, chlorite, epidote, magnetite, and orthoclase. Accessory minerals can include hematite, pyrite, quartz, rutile, titanite, tourmaline, white mica, and zircon. The proportions of minerals in a representative least-altered silica-poor diorite–monzodiorite sample are displayed in Figure 11F.

4.1.8.2.2 Textures

The silica-poor diorite–monzodiorite is typically equigranular and medium-grained (1–5 mm; Figure 35B). It is also characterized by substantial carbonate content (~25 vol%; Figure 11F). Carbonate minerals take the form of xenoblastic interstitial grains, larger subidioblastic grains (Figure 35B), and as mm- to cm-scale carbonate veinlets. Hematite alteration is occasionally associated with these carbonate veinlets. Plagioclase is typically subhedral and altered by chlorite, epidote, carbonates, and white mica (Figure 35B). Biotite is often altered by chlorite but, in some cases, biotite appears to overprint chlorite (Figure 35B). Magnetite is closely associated with hematite. Carbonates, biotite, chlorite, epidote, hematite, quartz, rutile, titanite, white mica, and occasionally magnetite are often intergrown and commonly replace

most other minerals excluding tourmaline (Figure 35B). Tourmaline overprints all minerals and, when present, is typically concentrated along structures such as shear planes and veinlets.

4.1.8.2.3 Primary minerals

Major primary minerals in the silica-poor diorite–monzodiorite, in approximate order of abundance, include plagioclase (oligoclase), biotite, magnetite, and orthoclase. Accessory primary minerals can include pyrite, quartz, white mica, and zircon. Some of the biotite is primary while some is likely alteration-derived. This is made apparent by the presence of some unaltered biotite grains in least-altered samples overprinting pre-existing chlorite (Figure 35B). It is unclear whether these unaltered biotite grains formed during metamorphism or due to another alteration event. Based on mineral modes determined via petrographic point counting techniques, this lithology plots in the diorite field of the QAP diagram (Figure 27).

4.1.8.3 Altered samples

4.1.8.3.1 Mineralogy

The mineralogy of a silica-poor diorite–monzodiorite sample altered by a V_3 vein (Figure 34B; Figure 35), in approximate order of abundance, consists mainly of plagioclase, carbonate minerals, chlorite, magnetite, and orthoclase. Based on visual petrographic estimates, this sample (T245) altered by non-auriferous V_3 veins displays notable increases in the amount of chlorite and white mica when compared to least-altered samples. In addition, biotite and epidote modes are significantly lower in the altered sample relative to least-altered samples. Proportions of other minerals remain similar to the proportions in least-altered samples. Based on macroscopic visual estimates, silica-poor dioritic–monzodioritic samples altered by V_3 veins with adjacent V_1-V_2 veins have more white mica (Figure 34A) than silica-poor dioritic–monzodioritic samples altered by V_3 veins with no adjacent V_1-V_2 veins (Figure 34B).

4.1.8.3.2 Textures

Some white mica, carbonate, and chlorite grains overprint or alter primary and pre-existing metamorphic minerals present in the least-altered samples of silica-poor diorite–monzodiorite. White mica grains are often randomly oriented and not parallel to the dominant foliation (Figure 35A). Biotite is present only in minor quantities and is often located at the core

of grains that are almost entirely replaced by chlorite (Figure 35A). Plagioclase is typically subhedral and altered by chlorite, epidote, carbonates, and white mica (Figure 35A). Pyrite is the dominant sulphide mineral and typically concentrates near ferromagnesian minerals (Figure 35A). Carbonates are interstitial or overgrow primary and metamorphic minerals. On average, this altered sample has a finer grain size than other least-altered samples.

4.1.8.3.3 V_3-vein related alteration minerals

The minerals that form in the silica-poor diorite–monzodiorite as a result of V_3 vein-related alteration and replace primary and pre-existing metamorphic minerals are mainly white mica, carbonate minerals, and chlorite.

4.1.9 Diabase–quartz diabase (I3DD)

4.1.9.1 Field observations

Diabase–quartz diabase dykes at the Island Gold deposit are typically aphanitic at the margins and medium grained closer to the centre. Unlike the other lithologies at this deposit, the diabase–quartz diabase has not been subject to substantial metamorphism or deformation (Figure 36A). These intrusions occasionally host xenoliths of granitoid rock that do not correspond with any lithologies observed at the Island Gold deposit (Figure 36B). These mafic intrusions crosscut the dacite, iron formation, gabbro, Webb Lake stock, gabbro/lamprophyre, and silica-poor diorite–monzodiorite. This lithology sharply cuts V_1-V_2 auriferous quartz veins and V_3 veins at a high-angle and shows no evidence of quartz vein-related alteration (Figure 36C, D). North of the Island Gold deposit, the diabase–quartz diabase dykes also cross-cut the mafic volcanic rocks and large intrusive bodies such as the Herman Lake Stock and the Maskinonge Lake Stock.

4.1.9.2 Mineralogy

The mineralogy of the diabase–quartz diabase, in approximate order of abundance, consists of plagioclase (andesine–labradorite), clinopyroxene, orthopyroxene, magnetite, actinolite, chlorite, biotite, quartz, hornblende, and epidote. Accessory minerals include carbonate minerals, and white mica. Proportions of minerals in a representative diabase–quartz diabase sample are displayed in Figure 11G. Carbonate mineral content is low in this lithology compared to most other lithologies at this deposit (Figure 11).

4.1.9.3 Textures

The diabase–quartz diabase is equigranular and fine to medium-grained (< 3 mm; Figure 36; Figure 37). Plagioclase is typically euhedral and slightly replaced by fine-grained chlorite, epidote, carbonates, and white mica (Figure 37). Quartz is also present and is unstrained. Potassium feldspars were not observed. Anhedral–subhedral magnetite is disseminated throughout these rocks as well (Figure 37). Pyroxene is subhedral–euhedral and grains are often slightly altered around their margins by actinolite and chlorite (Figure 37). Minor hornblende was often altered by actinolite and chlorite as well. Biotite typically overprints or is intergrown with this actinolite and chlorite alteration of both pyroxene and hornblende (Figure 37). Chlorite often alters the edges of biotite grains as well (Figure 37). Minor actinolite, biotite, carbonates, chlorite, epidote, and white mica alter or overprint most other minerals (Figure 37).

4.1.9.4 Primary minerals

Major primary minerals in the diabase–quartz diabase, in approximate order of abundance, consist of plagioclase (andesine–labradorite), clinopyroxene, orthopyroxene, magnetite, quartz, and hornblende. Based on mineral modes determined via petrographic point counting techniques, this lithology plots on the boundary of the quartz gabbro/quartz diorite and gabbro/diorite fields of the QAP diagram (Figure 27). Based on SEM-EDS analyses of plagioclase in this lithology, a larger proportion the plagioclase plots closer to the anorthite endmember than albite member (An > 50%) which supports the gabbroic classifications.

4.1.10 Greenschist-facies metamorphism

All lithologies at the Island Gold deposit were affected by metamorphism. Least-altered samples of all lithologies have metamorphic minerals which typically replace primary minerals. Depending on the protolith, these main metamorphic minerals may include actinolite, carbonates (mainly calcite), chlorite (ripidolite), chloritoid, epidote, hematite, ilmenite, magnetite, quartz, sodic plagioclase, titanite, and white mica (Sections 4.1.1 to 4.1.9). Textural relationships of these metamorphic minerals are summarized in this section based on observations detailed in Sections 4.1.1 to 4.1.9. Many of these minerals are typical greenschist-facies metamorphic minerals. These metamorphic minerals occasionally overprint or replace minerals derived from auriferous quartz vein-related alteration as well. However, alteration assemblages produced as a

result of gold mineralization appear well-preserved and are only weakly affected by later metamorphism. Occasionally, biotite may also be derived from metamorphism in the iron formation, silica-poor diorite-monzodiorite, and diabase-quartz diabase as it is sometimes observed intergrown with or overprinting metamorphic minerals in these lithologies (e.g. Figure 35). Ilmenite, magnetite, and titanite are typically present in trace amounts and replace primary iron-bearing minerals. Primary magnetite and ilmenite are also present in most lithologies but based on petrographic observations these minerals are dominantly metamorphic. Rutile is occasionally present in some least-altered samples but is more common in samples altered by quartz veins. This suggests rutile is mainly produced by quartz vein-related alteration but trace amounts may be produced due to metamorphism as well. Although not a greenschist-facies mineral, metamorphic grunerite is present in trace amounts in one least-altered dacitic sample.

Ferromagnesian minerals such as pyroxene, hornblende, and biotite are often replaced by chlorite and actinolite. Epidote, carbonates, and white mica typically replace plagioclase. In mafic-ultramafic lithologies, quartz and sodic plagioclase often overprint primary minerals indicating quartz and sodic plagioclase formed as a result of metamorphism in these lithologies. Hematite is occasionally associated with carbonate veinlets which are common throughout the deposit but have no observed spatial correlation with ore zones. Carbonate minerals, including those within these carbonate veinlets, were likely a product of metamorphism because they overprint primary minerals but are often overprinted by alteration minerals associated with V_1-V_2 and V_{GD} veins. The close association of hematite with these carbonate veinlets suggests that hematite can be metamorphic in origin. Chloritoid is sporadically present, and it overprints other metamorphic minerals and is often randomly oriented, suggesting that it also post-dates most deformation and represents late metamorphic growth. In rare cases, garnet is present and was observed closely associated with and replacing chloritoid. Based on this overprinting relationship, it is likely that garnet was generated after chloritoid potentially during late metamorphism as well. Alternatively, chloritoid and garnet may have been produced during a later alteration event unrelated to metamorphism.

4.2 Whole-rock geochemistry

In this section, the results of whole-rock geochemical study are summarized for nine lithologies: quartz (± carbonate) veins, dacite, iron formation, gabbro, the Webb Lake stock, gabbro/lamprophyre, quartz diorite, silica-poor diorite–monzodiorite, and diabase–quartz diabase. If certain lithologies have results from both least-altered samples and samples subject to alteration related to quartz ± carbonate veining, results pertaining to least-altered and altered samples are presented in separate sub-sections.

Major element concentrations in least-altered samples from each lithology at the Island Gold deposit are summarized in Table 17A, B. Averages and ranges are based off of the following least-altered and weakly-altered samples of each lithology: Dacite (8 samples: T8, T11, T65, T116, T154, T164, T183, T241), iron formation (2 samples: T24, T37), gabbro (5 samples: T14, T80, T89, T182, T200), Webb Lake stock (3 samples: T6, T192, T193), gabbro/lamprophyre (5 samples: T15, T63, T81, T239, T240), quartz diorite (1 sample: T215), silica-poor diorite–monzodiorite (5 samples: T16, T66, T216, T228, T242), and diabase-quartz diabase (2 samples: T12, T83). Diagrams used to classify least-altered samples in this section (4.2) also use these samples. T6 and T193 (Webb Lake stock) are classified as weakly-altered (Section 3.2.3).

4.2.1 Auriferous veins (V_{GD} and V_1-V_2 veins)

The compositions of V_{GD} and V_1-V_2 veins are summarized in Table 18 in Section 4.2. Samples of V_{GD} and V_1-V_2 quartz veins are characterized by high concentrations of SiO_2 (80.4–96.6 wt%). These samples also have economic concentrations of gold ranging from 2.1 to 50.5 ppm.

4.2.2 Dacitic volcanic rocks (T2, V2, I2)

4.2.2.1 Least-altered samples

Concentrations of chemical species in least-altered dacitic volcanic samples are summarized in Table 17. These dacitic samples are sodium rich (2.1–5.8 wt% Na_2O) and potassium poor (0.5–1.3 wt% K_2O). The four least-altered dacitic samples have smooth negatively-sloping chondrite-normalized REE patterns with no Eu or Ce anomalies. Chondrite-normalized patterns of the heavy REE (Ho–Lu) are flat (Figure 40).

On a Total-Alkali Silica (TAS) diagram, least-altered samples of this lithology consistently plot within the dacite field (Figure 38A; Le Bas et al., 1986). They also plot within the dacite and rhyodacite fields of the R_1-R_2 multi-cationic plot (Figure 38B; De La Roche et al., 1980). However, these samples have been subject to metamorphism. To verify the classifications suggested by these plots, immobile element classifications plots were also used. These least-altered samples plot within both the dacite/rhyolite and the andesite/basaltic andesite fields of the Co-Th plot (Figure 39A; Hastie et al., 2007). They also plot within the andesite/basaltic andesite field of the Nb/Y-Zr/Ti plot (Figure 39B; Pearce, 1996).

4.2.2.2 Altered samples

Average concentrations of chemical species in volcanic samples classified under each alteration strength grouping and altered by proximal V_1-V_2 veins are presented alongside mass balance calculations in Table 5. Similarly, average concentrations of chemical species in volcanic samples classified under each alteration strength grouping and altered by proximal V_{GD} veins are presented in Table 6. Average concentrations of these chemical species in equivalent least-altered samples are also included in these tables for comparison. Concentrations of chemical species in a dacitic sample (T218) subject to non-auriferous carbonate-sericite alteration are displayed in Appendix N. Concentrations of select chemical species in T218 are also displayed alongside mass balance calculations in Table 7.

4.2.2.2.1 Isocon diagrams

Isocon diagrams (Grant, 1986; Section 3.2.2) are used in this section in order to determine and display consistent chemical enrichments and depletions as a result of the alteration of the dacite. An Isocon diagram was constructed for each altered/less-altered pair from volcanic-hosted alteration envelopes associated with V_1-V_2 auriferous veins at the locations shown in Figure 19. A volcanic-hosted alteration envelope associated with a V_{GD} vein in the Goudreau Zone is also examined via Isocon diagram analysis (Figure 42). Chemical gains and losses determined by examining the Isocon diagrams of altered/less-altered pairs from each alteration envelope are summarized in Table 4 and Appendix S. The chemical gains/losses for each alteration envelope are based on multiple altered/less-altered pairs from the same alteration

envelope (Table 4). The chemical gains/losses that are verified by multiple altered/less-altered pairs from the same alteration envelope are more reliable (discussed in Section 3.2.2).

An average Isocon diagram was created to summarize chemical gains/losses as a result of alteration related to V_1-V_2 veins throughout the deposit. A representative altered/less-altered pair was selected from each of the five V_1-V_2 vein-related alteration envelopes outlined in Figure 19. An Isocon diagram was then constructed based on the average chemical composition of altered samples and the average chemical composition of less-altered samples (Figure 41). Chemical gains and losses that were consistently observed in each alteration envelope associated with V_1-V_2 veins are displayed. Chemical species that are typically enriched in dacite due to alteration related to V_{GD} or V_1-V_2 veins include As, Au, Bi, K_2O, Rb, S, Se, Te, Tl, and W while depletions include Na_2O and Sr (Table 4).

Carbonate-sericite volcanic-hosted alteration zones that are gold-barren are occasionally observed at the Island Gold deposit. This type of alteration has a superficial resemblance to auriferous alteration and the mineralogy of these zones is discussed in Section 4.1.2. A representative Isocon diagram that displays the chemical gains/losses that consistently occur based on multiple altered/less-altered pairs associated with this type of alteration is displayed in Figure 43 and summarized in Table 4. Notably, there is no consistent enrichment in As, Te, Tl, or W and no consistent loss of Sr or Na_2O (Table 4). Enrichments and depletions of these chemical species are commonly associated with auriferous quartz veining at the Island Gold deposit (Table 4).

4.2.2.2.2 Mass balance calculations

Mass balance calculations (Section 3.2.4) are used in this section to quantify the magnitude of enrichment and depletion of chemical species due to the alteration of dacite. The chemical compositions of samples classified under each alteration strength grouping were first averaged and then compared to the average chemical composition of least-altered samples taken from throughout the deposit. Calculations were performed separately for dacitic samples altered by V_1-V_2 veining (Table 5) and for dacitic samples altered by V_{GD} veins (Table 6). Average concentrations of chemical species (C) for samples classified in each alteration strength grouping as well as the calculated concentration changes (ΔC) of chemical species are displayed. Concentration changes of chemical species relative to their concentration in the least-altered

sample are also displayed in this table ($\Delta C/C_{LA}$). Al_2O_3, Hf, Nb, Th, TiO_2, Y, and Zr were selected as immobile for calculations involving samples altered by V_1-V_2 veining. Al_2O_3, Th, TiO_2 and Zr were selected as immobile for samples altered by V_{GD} veins. Chemical species that are significantly enriched in strongly-altered samples due to V_1-V_2 vein-related alteration include Au, S, W, As, Te, Bi, K_2O, B, Rb, Fe_2O_3, Cs, Mo, and LOI (Table 5). Similarly, chemical species that are notably enriched due to V_{GD} vein-related alteration include Au, As, S, Te, Bi, W, K_2O, B, Fe_2O_3, Rb, CO_2, C, Cs, Cu, and LOI (Table 6).

Mass balance was also used to compare the magnitude of gains/losses associated with the non-auriferous carbonate-sericite alteration to the alteration associated with auriferous quartz veins. The chemical compositions of the representative altered and least-altered samples, used in the Isocon diagram displayed in Figure 43 (Section 4.2.2.2.1), are used for these calculations. Only gains/losses of chemical species that are observed to be consistently enriched or depleted in Section 4.2.2.2.1 are displayed. Concentration changes of chemical species relative to their concentration in the least-altered sample ($\Delta C/C_{LA}$) are displayed in Figure 44 and summarized in Table 7. Altered and least-altered concentrations as well as the calculated concentration changes (ΔC) of chemical species are also displayed in Table 7. Despite this intense alteration, concentration changes are negligible for many of the chemical species that are consistently and significantly enriched due to alteration associated with V_1-V_2 and V_{GD}. For example, ΔC is only 0.01 ppm for both Au and S. Chemical species that are significantly enriched due to carbonate-sericite alteration include C, CO_2, LOI, B, and CaO (Table 7).

4.2.3 Iron formation (IF)

Compositions of least-altered iron formation samples are summarized in Table 17. Relative to other lithologies at the Island Gold deposit, samples of iron formation are characterized by high average concentrations of Fe_2O_3 (43.8 wt%), FeO (18.5 wt%), and S (30.8 wt%).

4.2.4 Gabbro (I3G)

4.2.4.1 Least-altered samples

This lithology has 44.1–48.7 wt% SiO_2 and is generally characterized by higher total iron (12.0–14.4 wt% Fe_2O_3T) and TiO_2 (0.6–1.2 wt%) concentrations than the gabbro/lamprophyre

(Table 17B). They also have lower average MgO (6.7 wt%), Cr (132 ppm), and Ni (115 ppm) concentrations when compared to gabbro/lamprophyre (Table 17A). Least-altered samples are also potassium deficient (0.01–0.12 wt% K_2O). Four representative least-altered samples have flat chondrite-normalized REE patterns with a slight negative Eu anomaly in T89, a slight positive Eu anomaly in T200, and no Ce anomalies (Figure 40B).

Least-altered samples with mineral modes determined via CIPW Norm calculations fall in the tonalite and gabbro fields of the QAP diagram (Figure 45). Least-altered samples with the most primary textures (T182 and T200) plot closer to the plagioclase apex in the lower tonalite and gabbro fields of the QAP diagram (Figure 45). On a TAS diagram modified for intrusive lithologies, these samples fall in the subalkalic gabbro field (Figure 46A; Middlemost, 1994). The least-altered samples of this lithology fall in the gabbro-norite, gabbro-diorite, and diorite fields of the R_1, R_2 multi-cationic plot (Figure 46B; De La Roche et al., 1980) and in the quartz diorite and tonalite fields of the P-Q diagram (Figure 46C; Debon and Le Fort, 1983). However, these samples have also been subject to significant metamorphism. As a result, immobile element plots are also used to support these classifications. On the immobile element ratio plot that was modified for intrusive lithologies, these samples all plot in the gabbro field (Figure 46D; Nb/Y, Zr/TiO_2; Pearce, 1996).

4.2.4.2 Altered samples

Average concentrations of chemical species in gabbroic samples classified under each alteration strength grouping and altered by proximal V_1-V_2 veins are presented alongside mass balance calculations in Table 8. The average concentrations of chemical species in equivalent least-altered samples are also included for comparison.

4.2.4.2.1 Isocon diagrams

Isocon diagrams (Section 3.2.2) are used in this section in order to determine and display consistent chemical enrichments and depletions as a result of alteration related to V_1-V_2 veining. Isocon diagrams were constructed for altered/less-altered pairs from a gabbro-hosted alteration envelope associated with V_1-V_2 auriferous quartz veining. Results of the analysis of these diagrams are summarized in Table 4 and Appendix S. An Isocon diagram for a representative altered/less-altered pair is displayed in Figure 47. Only chemical species that consistently exhibit

gains/losses based on Isocon analysis of multiple altered/less-altered pairs are displayed. Chemical species that are consistently enriched in gabbro due to alteration related to V_1-V_2 veins include Au, B, Ba, Cs, K_2O, Li, MnO, Pb, Rb, S, Sm, Sr, and Te. Consistent depletions include Bi, Ge, Na_2O, P_2O_5, Sb, and Tl (Table 4).

4.2.4.2.2 Mass balance calculations

Mass balance calculations (Section 3.2.4) are used in this section to quantify the magnitude of enrichment and depletion of chemical species due to the V_1-V_2 vein-related alteration of gabbro. The chemical composition of samples classified under each alteration strength grouping from the same gabbro-hosted alteration envelope were first averaged and then compared to the average chemical composition of least-altered samples taken from throughout the deposit. Mass balance calculations were performed and the results are summarized in Table 8. Al_2O_3, Er, Nb, and Zr were selected as immobile for calculations. Chemical species that are significantly enriched in the strongly-altered sample due to V_1-V_2 vein-related alteration include Au, S, B, Bi, K_2O, As, Ba, Te, Rb, W, Se, Cs, and Tl (Table 8).

4.2.5 Webb Lake stock: Tonalite–trondhjemite (I1JM)

4.2.5.1 Least-altered samples

This felsic intrusion (66.2–71.5 wt% SiO_2) is rich in sodium (4.5–4.9 wt % Na_2O) and is comparatively potassium poor (0.9–1.1 wt % K_2O; Table 17). Al_2O_3 concentrations range from 13.9–15.3 wt% while CaO concentrations range from 2.7–4.5 wt%. These are generally consistent with Archean tonalite-trondhjemite-granodiorites (TTG; Barker, 1979; Moyen and Martin, 2012). The sum of the average MgO, TiO_2, Fe_2O_3T, and MnO concentrations for Webb Lake stock samples equates to 5.2 wt% (Table 17) while Archean TTGs typically have ≤5.0 wt% (Moyen and Martin, 2012). A least-altered and a weakly-altered sample of the Webb Lake stock have smooth chondrite-normalized REE patterns with steep negative slopes (left of Y), no Eu or Ce anomalies, and heavy REE patterns are flat (Figure 40C).

Least-altered and weakly-altered samples with mineral modes determined via CIPW Norm calculations fall in the tonalite field of the QAP diagram (Figure 45). Difficulty distinguishing the composition of each plagioclase makes point-counting techniques inappropriate for plotting on the Anorthite-Albite-Orthoclase ternary diagram. Using mineral

modes determined by CIPW Norm calculations, these samples plot in the trondhjemite field of the Anorthite-Albite-Orthoclase ternary diagram (Figure 48). On a TAS diagram modified for intrusive lithologies these samples plot in the granodiorite and granite fields (Figure 46A). Least-altered and weakly-altered samples of this lithology fall in the granodiorite field of the R_1, R_2 multi-cationic plot (Figure 46B) and the tonalite field of the P-Q classification diagram (Figure 46C). On the immobile element ratio plot, that was modified for intrusive lithologies, these samples all plot in the diorite-gabbro diorite field (Figure 46D; Nb/Y, Zr/TiO_2). A tonalite field is not delineated on this diagram.

4.2.5.2 Altered samples

Concentrations of chemical species in representative samples of the Webb Lake stock classified under each alteration strength grouping and altered by proximal V_1-V_2 veins are presented alongside mass balance calculations in Table 9. The average concentrations of chemical species in equivalent least-altered samples are also included for comparison.

4.2.5.2.1 Isocon diagrams

Isocon diagrams (Section 3.2.2) are used in this section in order to determine and display consistent chemical enrichments and depletions as a result of alteration related to V_1-V_2 veining. Isocon diagrams were constructed for altered/less-altered pairs from a Webb Lake stock-hosted alteration envelope associated with V_1-V_2 auriferous quartz veining. Results of the analysis of these diagrams are summarized in Table 4 and Appendix S. An Isocon diagram for a representative altered/less-altered pair is displayed in Figure 49. Only chemical species that consistently exhibit gains/losses based on Isocon analysis of multiple altered/less-altered pairs are displayed. Chemical species that are consistently enriched in the Webb Lake stock due to alteration related to V_1-V_2 veins include Ag, As, Au, B, Bi, C, CO_2, Cu, Fe_2O_3, Ge, K_2O, LOI, Mo, Rb, S, Se, Ta, Te, U, and W. Consistent depletions include CaO, Co, Fe_2O_3T, FeO, MnO, Na_2O, Sc, SiO_2, and Sm (Table 4).

4.2.5.2.2 Mass balance calculations

Mass balance calculations (Section 3.2.4) are used in this section to quantify the magnitude of enrichment and depletion of chemical species due to the V_1-V_2 vein-related

alteration of the Webb Lake stock. The chemical compositions of samples classified under each alteration strength grouping from the same Webb Lake stock-hosted alteration envelope were compared to the chemical composition of the least-altered sample taken just outside of the alteration envelope. Mass balance calculations were performed and the results are summarized in Table 9. Al_2O_3 and Y were selected as immobile for calculations. Chemical species that are significantly enriched in the strongly-altered sample due to V_1-V_2 vein-related alteration include As, S, Au, Te, Mo, B, W, Bi, Fe_2O_3, Cu, K_2O, Ag, and Rb (Table 9).

4.2.6 Gabbro/Lamprophyre (I2H)

4.2.6.1 Least-altered samples

The gabbro/lamprophyre at the Island Gold deposit contains 40.9–46.8 wt% SiO_2 and has a low concentration of K_2O (0.08–0.39 wt%). This unit is also characterized by high MgO (8.0–10.7 wt%), Cr (282–576 ppm), Ni (119–472 ppm), and CO_2 (11.5–15.7 wt%) concentrations compared to most other lithologies at the Island Gold deposit (Table 17). Four representative least-altered samples have smooth, steep, negatively-sloping chondrite-normalized REE patterns with no Eu or Ce anomalies and flat heavy REE patterns (Figure 40D).

Least-altered samples with mineral modes determined via CIPW Norm calculations fall in the tonalite field of the QAP diagram (Figure 45). One sample also plots in the granodiorite field (Figure 45). On a TAS diagram modified for intrusive lithologies these samples fall in the gabbro diorite and subalkalic gabbro fields (Figure 46A). The least-altered samples of this lithology plot within the gabbro-diorite, gabbro-norite, and gabbro fields on a R_1, R_2 multi-cationic plot (Figure 46B) and in the quartz diorite and gabbro fields of the P-Q diagram (Figure 46C). On the immobile element ratio plot, that was modified for intrusive lithologies, these samples all plot in the diorite and gabbro-diorite field (Figure 46D; Nb/Y, Zr/TiO_2).

4.2.6.2 Altered samples

Concentrations of chemical species in a sample of gabbro/lamprophyre (T213) altered by a V_3 vein are displayed in Appendix N. Concentrations of select chemical species in T213 are also displayed alongside mass balance calculations in Table 10.

4.2.6.2.1 Isocon diagrams

Isocon diagrams (Section 3.2.2) are used in this section in order to determine and display consistent chemical enrichments and depletions as a result of alteration related to V_3 veining. Two Isocon diagrams were constructed in which a sample of gabbro/lamprophyre altered by V_3 quartz veining is compared to representative least-altered equivalents. Only chemical species that were enriched or depleted in both altered/least-altered pairs are displayed in the representative Isocon diagram in Figure 50. Results are summarized in Table 4 and Appendix S.

The following chemical species were consistently enriched: As, Au, B, Ba, Bi, Ce, Cr, Cs, Ga, Ge, K_2O, La, Li, Mo, Rb, Sb, Sr, V, W, and Zn. The chemical species that are consistently depleted are Ag, C, CaO, Co, CO_2, Dy, Er, LOI, Lu, MgO, MnO, Na_2O, Ni, Pb, Se, SiO_2, Tb, Tm, Y, and Yb.

4.2.6.2.2 Mass balance calculations

Mass balance calculations (Section 3.2.4) are used in this section to quantify the magnitude of enrichment and depletion of chemical species due to the V_3 vein-related alteration of gabbro/lamprophyre. The chemical compositions of the representative altered and least-altered samples, used in the Isocon diagram displayed in Section 4.2.6.2.1 (Figure 50), are used for these calculations. Only gains/losses of chemical species that are observed to be consistently enriched or depleted (from Section 4.2.6.2.1) are displayed. Relative concentration changes determined via mass balance calculations are displayed graphically in Figure 51 and numerically in Table 10. Concentration changes associated with V_3 vein-related alteration are small for most chemical species that are consistently and significantly enriched due to alteration associated with V_1-V_2 and V_{GD} veins. For example, there is a concentration gain of only 0.05 ppm for Au (Table 10). Chemical species that are significantly enriched in the altered sample due to V_3 vein-related alteration include Ba, As, W, and Sr (Table 10).

4.2.7 Quartz diorite

A single sample of the quartz diorite is characterized by high SiO_2 (65.5 wt%), Al_2O_3 (16.7 wt%), and Na_2O (8.9 wt%), in addition to low K_2O (0.05 wt%) concentrations relative to other rock types at the Island Gold deposit (Table 17). The quartz diorite is also plotted on a chondrite-normalized REE diagram (Figure 40E). This sample has a smooth, steep, negative

slope that shallows rapidly in the middle REEs and becomes positive in the latter half of the heavy REEs (Figure 40E). This pattern has no Eu or Ce anomalies.

Using CIPW-calculated mineral modes, this lithology plots as a quartz diorite on a QAP ternary diagram (Figure 45). On a TAS diagram modified for intrusive lithologies, this sample falls in the quartz monzonite field (Figure 46A). When plotted on the R_1, R_2 multi-cationic plot (Figure 46B), it falls in the quartz syenite field. This sample does not plot within any of the defined fields on the P-Q diagram (Figure 46C). On the immobile element ratio plot that was modified for intrusive lithologies, this sample plots in the syenite field (Figure 46D; Nb/Y, Zr/TiO_2).

4.2.8 Silica-poor diorite–monzodiorite (I2M)

4.2.8.1 Least-altered samples

The silica-poor diorite–monzodiorite has the lowest SiO_2 content out of all the chemically analyzed lithologies at the Island Gold deposit (37.9–45.9 wt%; Table 17). It is also characterized by high Na_2O (3.4–5.5 wt%) and CaO (9.9–13.6 wt%) concentrations relative to most lithologies at the Island Gold deposit (Table 17). Four representative least-altered samples have a smooth, negatively-sloping, chondrite-normalized REE patterns with no Eu or Ce anomalies (Figure 40F). Their slopes become shallower to the right of Y. When compared to the REE patterns of other lithologies, the silica-poor diorite–monzodiorite generally exhibits the highest concentrations of REEs relative to the other rock types at the Island Gold deposit.

Least-altered samples with mineral modes determined via CIPW Norm calculations fall in the quartz diorite and diorite fields of the QAP diagram (Figure 45). All of the least-altered samples are also plotted on a TAS diagram modified for intrusive lithologies and these samples fall in the monzo-diorite, monzo-gabbro, and foid-gabbro fields (Figure 46A). On the R_1, R_2 multi-cationic plot (Figure 46B), the least-altered samples of this lithology fall in the theralite and essexite fields. These same samples do not plot within any of the defined fields on the P-Q diagram (Figure 46C). On the immobile element ratio plot that was modified for intrusive lithologies, these samples all plot in the monzonite and diorite, as well as gabbro-diorite fields (Figure 46D; Nb/Y, Zr/TiO_2).

4.2.8.2 Altered samples

Concentrations of chemical species in a silica-poor dioritic–monzodioritic sample (T245) altered by V_3 veining are displayed in Appendix N. Concentrations of select chemical species in T245 are also displayed alongside mass balance calculations in Table 11.

4.2.8.2.1 Isocon diagrams

Isocon diagrams (Section 3.2.2) are used in this section in order to determine and display consistent chemical enrichments and depletions as a result of alteration related to V_3 veining. Two Isocon diagrams were constructed in which a sample of silica-poor diorite–monzodiorite altered by V_3 quartz veining is compared to representative least-altered equivalents. Only chemical species that were consistently enriched or depleted in both altered/least-altered pairs are displayed in the representative Isocon diagram (Figure 52). Results are summarized in Table 4 and Appendix S.

The following chemical species were consistently enriched: As, Au, CaO, FeO, Hf, Li, S, Sc, Te, and W. Conversely, the chemical species consistently depleted are: B, Ba, C, CO_2, Cr, Cs, Cu, Fe_2O_3, Ga, K_2O, LOI, Mo, Na_2O, Ni, Pb, Rb, Sb, Se, Sr, and U.

4.2.8.2.2 Mass balance calculations

Mass balance calculations (Section 3.2.4) are used in this section to quantify the magnitude of enrichment and depletion of chemical species due to the V_3 vein-related alteration of the silica-poor diorite–monzodiorite.

The chemical compositions of the representative altered and least-altered samples, used in the Isocon diagram displayed in Section 4.2.8.2.1 (Figure 52), are used for these calculations. Only gains/losses of chemical species that are observed to be consistently enriched or depleted in Section 4.2.8.2.1 are displayed. Relative concentration changes of chemical species are displayed graphically in Figure 53 and numerically in Table 11. Concentration changes associated with this alteration are small for many of the chemical species that are consistently and significantly enriched due to alteration associated with V_1-V_2 and V_{GD}. For example, there is a concentration gain of only 0.07 and 0.15 ppm for Au and S, respectively (Table 11). Chemical species that are significantly enriched in the altered sample due to V_3 vein-related alteration include W and As (Table 11).

4.2.9 Diabase–quartz diabase (I3DD)

Relative to other lithologies at the Island Gold deposit, two samples of the diabase–quartz diabase have high average concentrations of total iron (1.4 wt% Fe_2O_3T), CaO (9.5 wt%), and TiO_2 (1.4 wt%; Table 17). Chondrite-normalized REE patterns have shallow negative slopes with minor Eu anomalies (Figure 40G). Right of Y, the slopes become flat or slightly positive.

Least-altered samples with mineral modes determined via CIPW Norm calculations fall in the quartz gabbro field of the QAP diagram (Figure 45). On a TAS diagram modified for intrusive lithologies, these samples fall in the subalkalic gabbro and gabbro diorite fields (Figure 46A). These samples plot in the gabbro-diorite field on the R_1, R_2 multi-cationic plot (Figure 46B) and the quartz diorite field of the P-Q diagram (Figure 46C). On the immobile element ratio plot that was modified for intrusive lithologies, these samples plot in the alkali gabbro and gabbro fields (Figure 46D; Nb/Y, Zr/TiO_2).

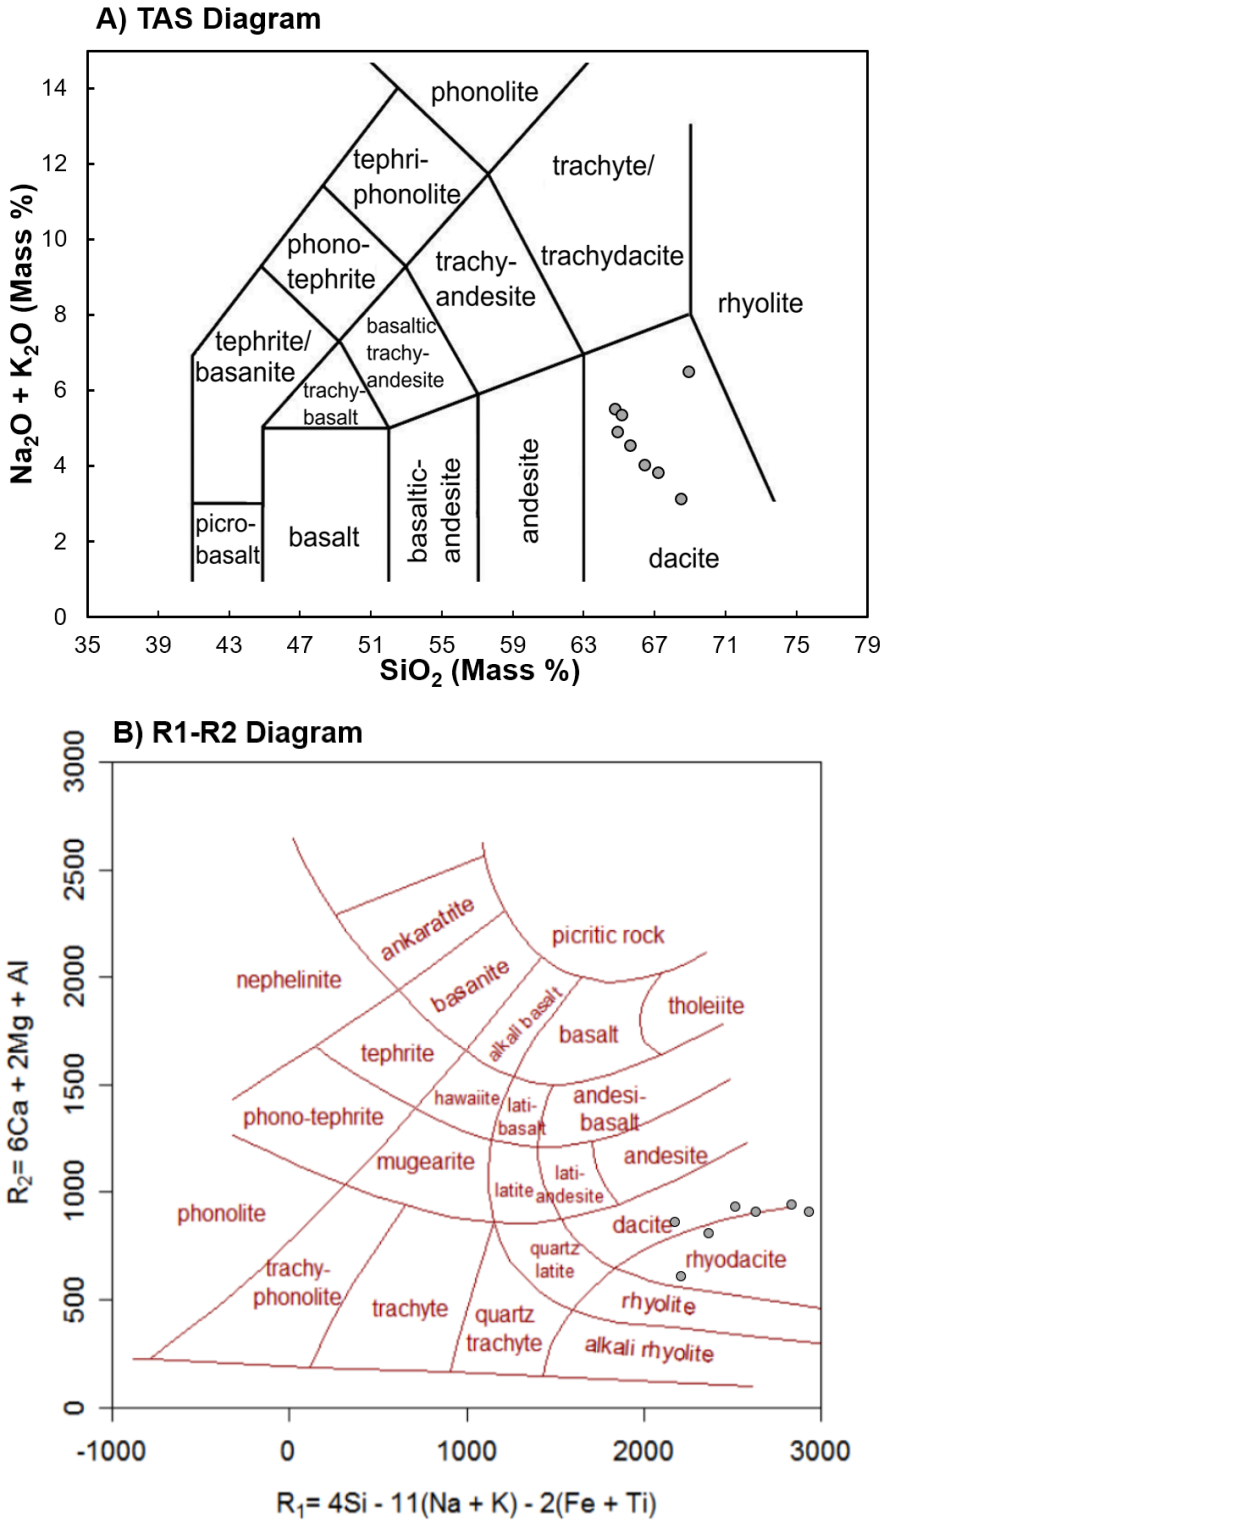

Figure 38A, B. *Least-altered dacitic samples (T8, T11, T65, T116, T154, T164, T183, T241) plotted on mobile element classification diagrams. A) Total Alkali Silica (TAS) diagram. Concentrations of oxides are normalized on a volatile-free basis to 100% before plotting. Modified from Le Bas et al. (1986) and Janoušek (2018). B) Least-altered dacitic samples (T8, T11, T65, T116, T154, T164, T183, T241) plotted on the R_1-R_2 multicationic plot modified from De La Roche et al. (1980) and Janoušek (2018).*

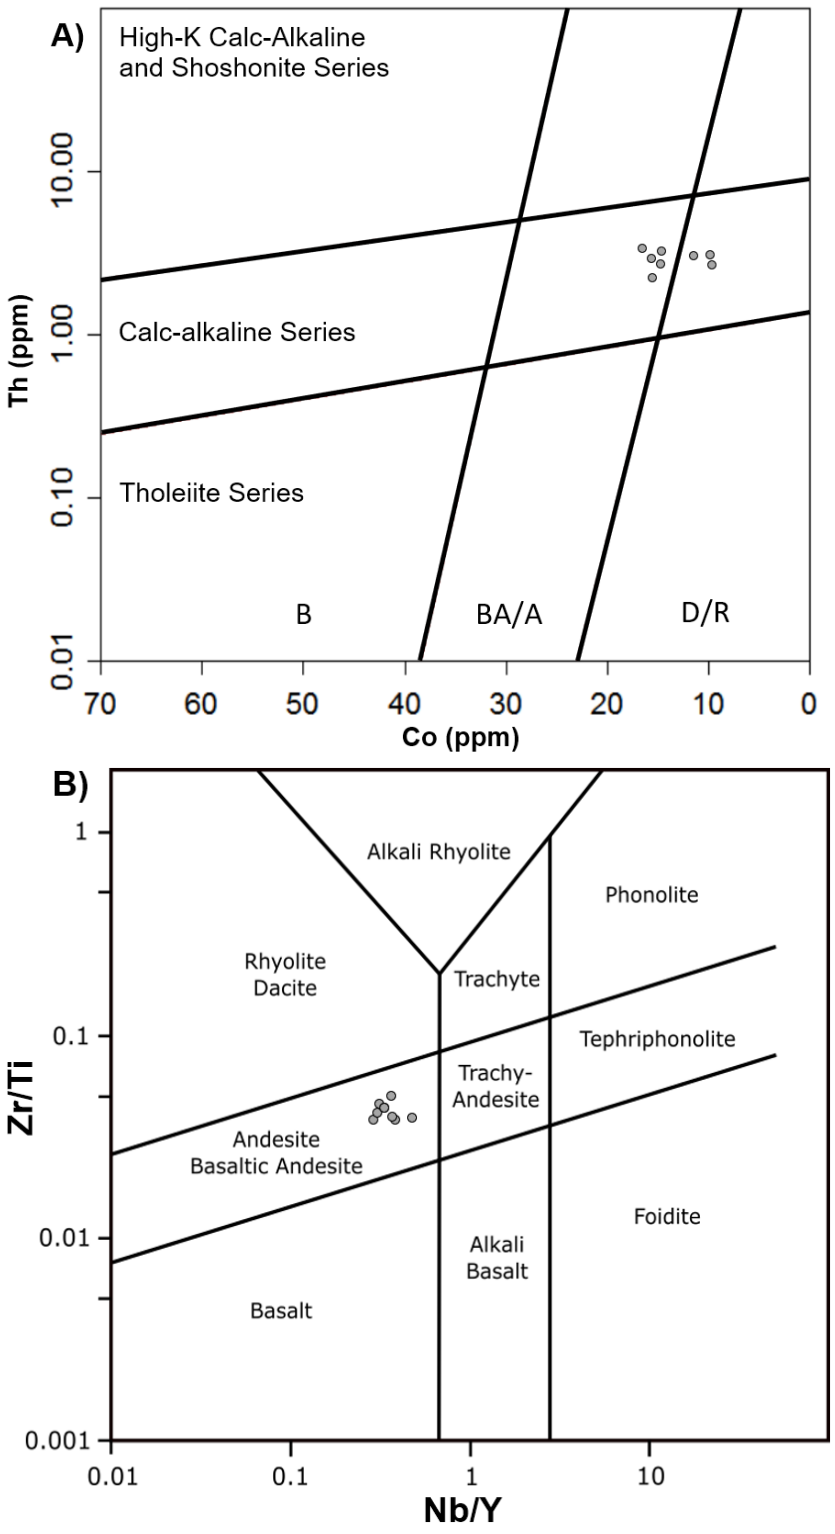

Figure 39A, B. *Least-altered dacitic samples (T8, T11, T65, T116, T154, T164, T183, T241) plotted on classification diagrams designed to classify volcanic rocks using relatively immobile elements. A) Co-Th diagram modified from Hastie et al. (2007) and Janoušek (2018). B=Basalt, BA/A=Basaltic Andesite/Andesite, D/R=Dacite/Rhyolite. B) Nb/Y-Zr/Ti diagram modified from Pearce (1996). This diagram is originally from Winchester and Floyd (1977) and was later revised in Pearce (1996). Modified from Janoušek (2018).*

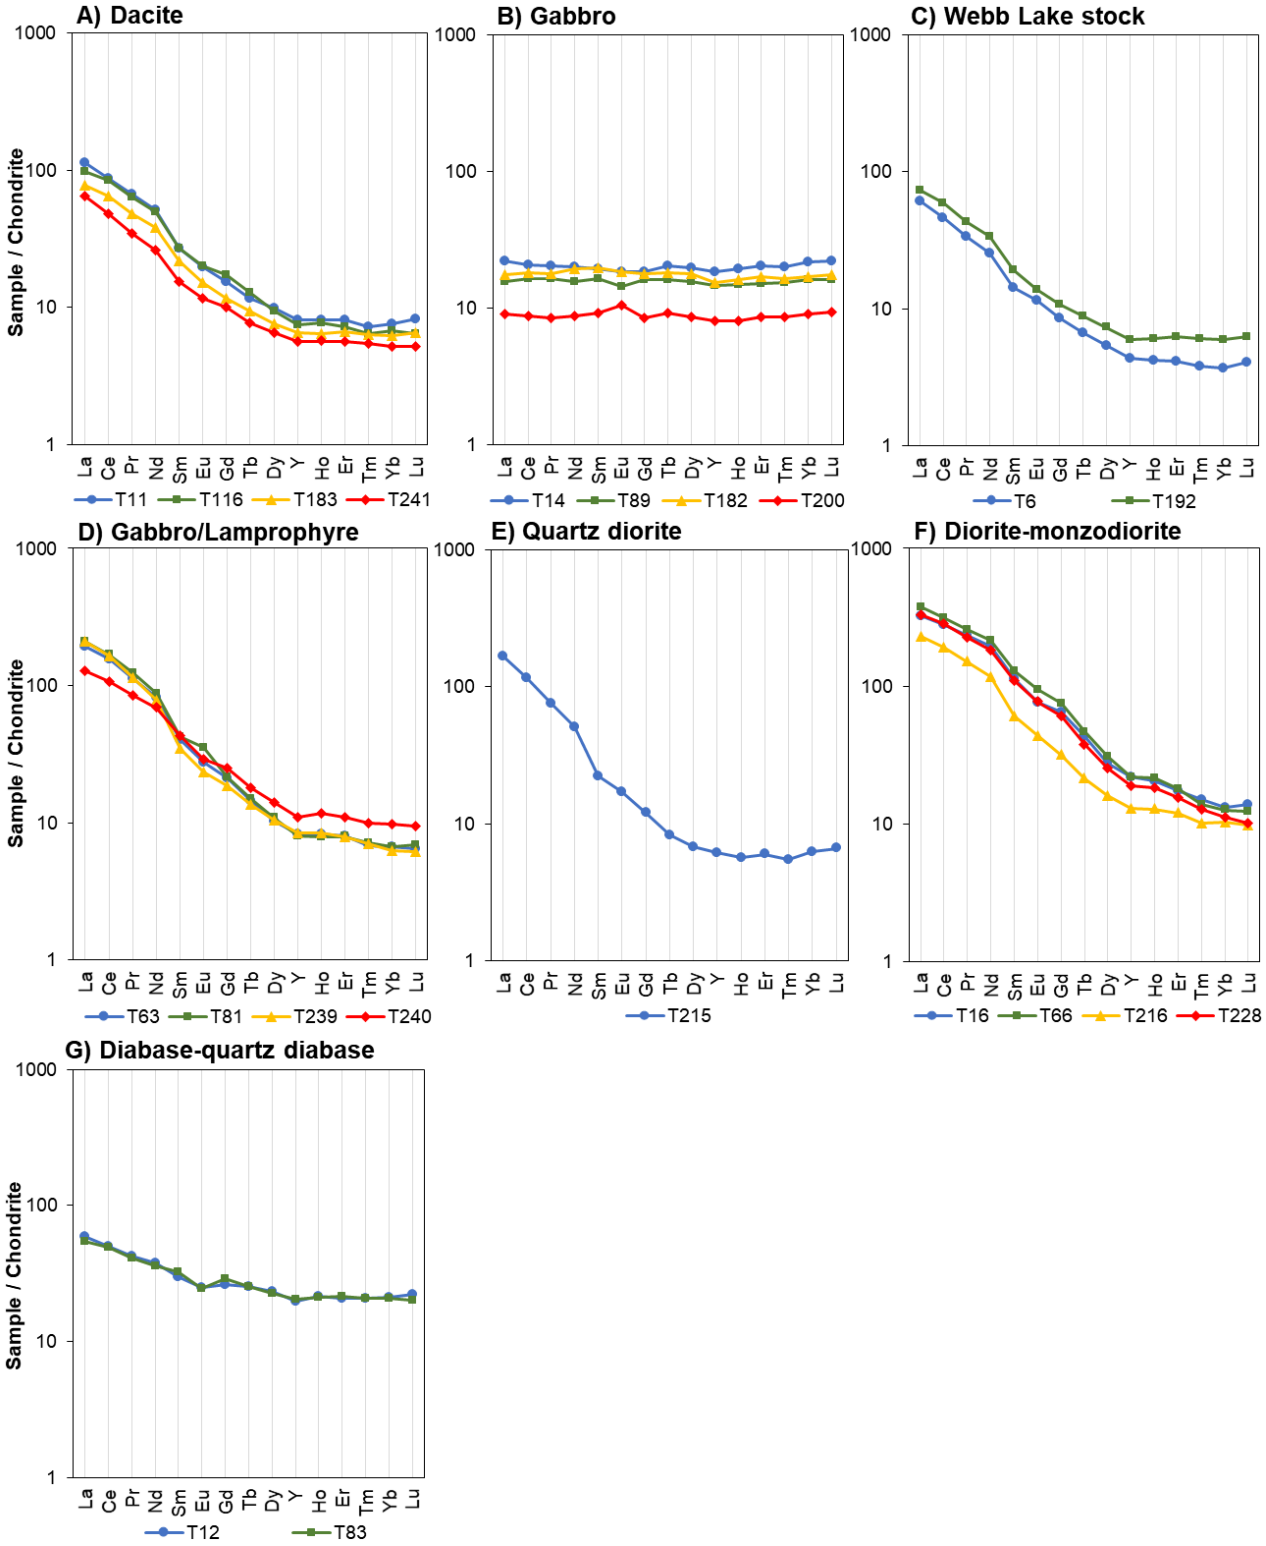

Figure 40A–G. *Representative least-altered intrusive and volcanic samples of various lithologies at the Island Gold deposit plotted on CI carbonaceous chondrite-normalized rare earth element diagrams with yttrium. The y-axis uses a* $\log_{10}$ *scale. Chondrite chemistry is from McDonough and Sun (1995).*

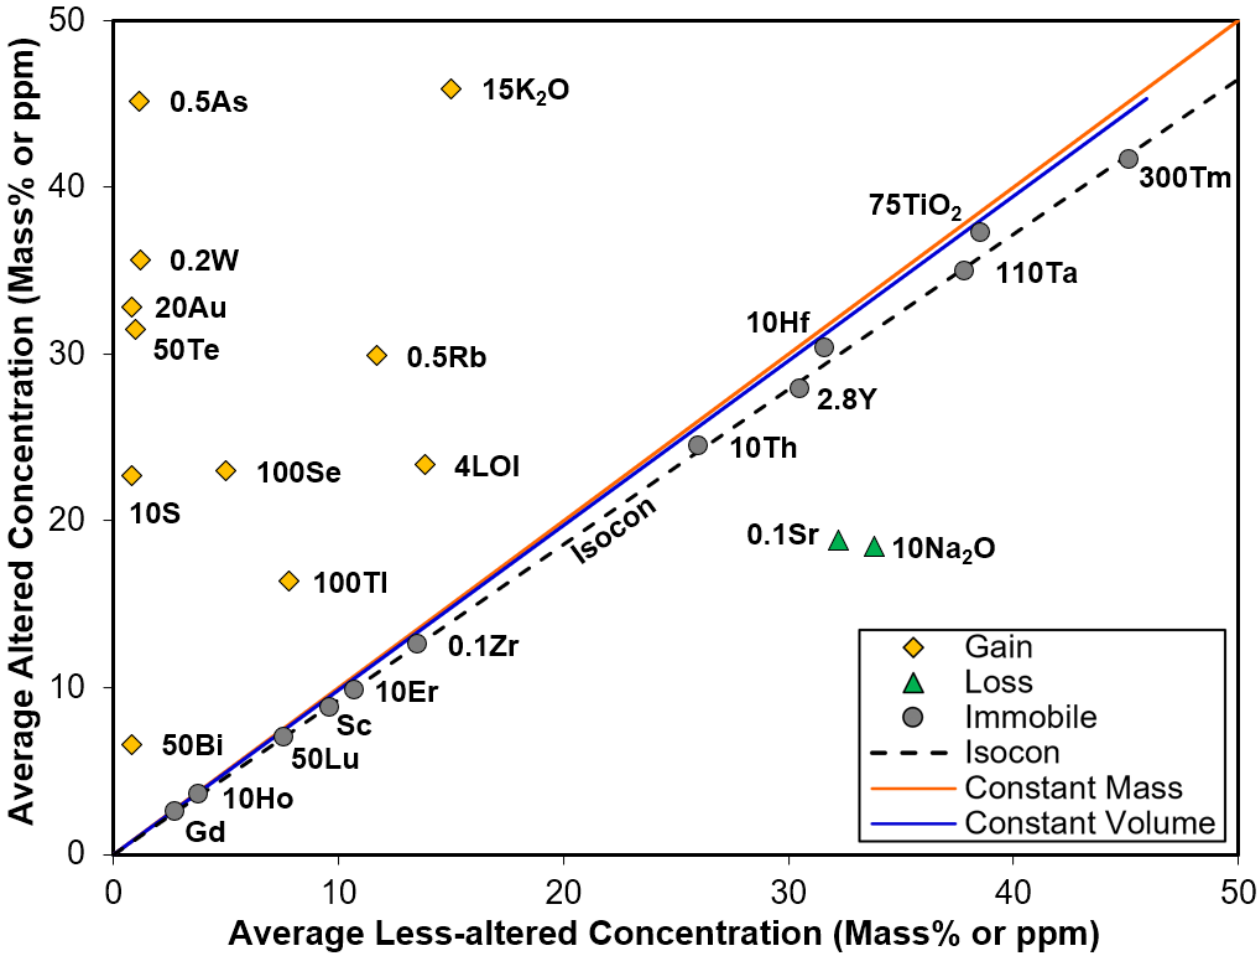

Figure 41. *Isocon diagram displaying the average chemistry of five altered dacitic samples (T58, T72, T157, T162, T188) from five ore zones dispersed throughout the deposit plotted against the average chemistry of five corresponding less-altered dacitic samples (T59, T65, T154, T164, T184). These ore zones and associated alteration envelopes are associated with V_1-V_2 auriferous veins. In addition to chemical species determined to be relatively immobile for this average altered/average less-altered pair, only chemical species that are consistently enriched or depleted, based on the study of multiple altered/less-altered pairs, are displayed. Concentrations of elements are arbitrarily scaled to avoid stacking/overlap. This is achieved by multiplying both the concentration of the chemical species in the altered sample and the concentration of the chemical species in the less-altered sample by the scale factor/multiplier shown beside each chemical species. LOI=Loss on ignition, Fe_2O_3T=Total Iron. The methods used to construct these diagrams are detailed in Section 3.2.2.*

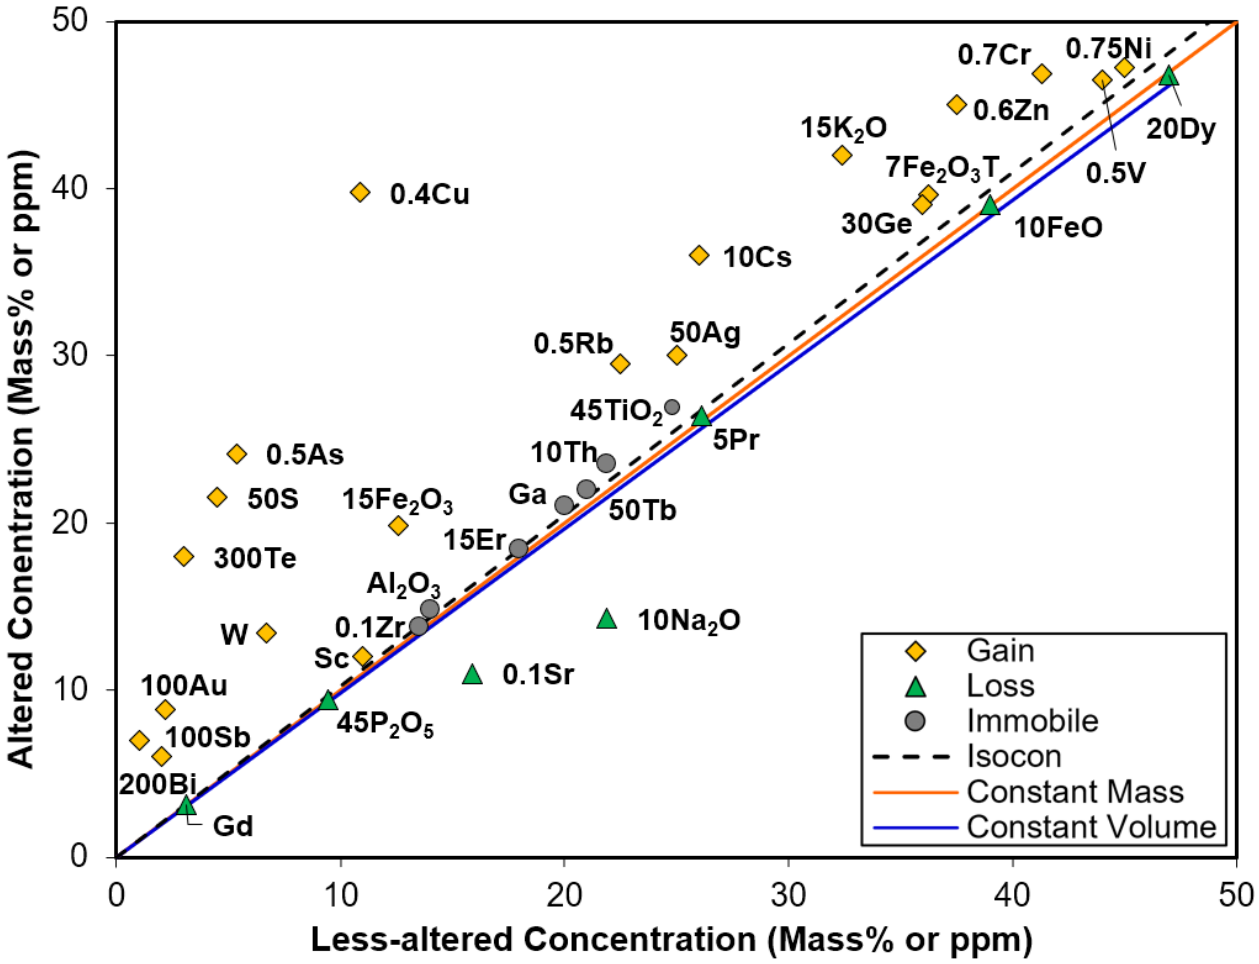

Figure 42. *Isocon diagram displaying an altered dacitic sample (T115) plotted against a less-altered dacitic sample (T114) from same alteration envelope. This alteration envelope is from the Goudreau Zone and is associated with a V_{GD} auriferous vein. In addition to chemical species determined to be relatively immobile for this altered/less-altered pair, only chemical species that are consistently enriched or depleted, based on the study of multiple altered/less-altered pairs, are displayed. Concentrations of elements are arbitrarily scaled to avoid stacking/overlap. This is achieved by multiplying both the concentration of the chemical species in the altered sample and the concentration of the chemical species in the less-altered sample by the scale factor/multiplier shown beside each chemical species. LOI=Loss on ignition, Fe_2O_3T=Total Iron. The methods used to construct these diagrams are detailed in Section 3.2.2.*

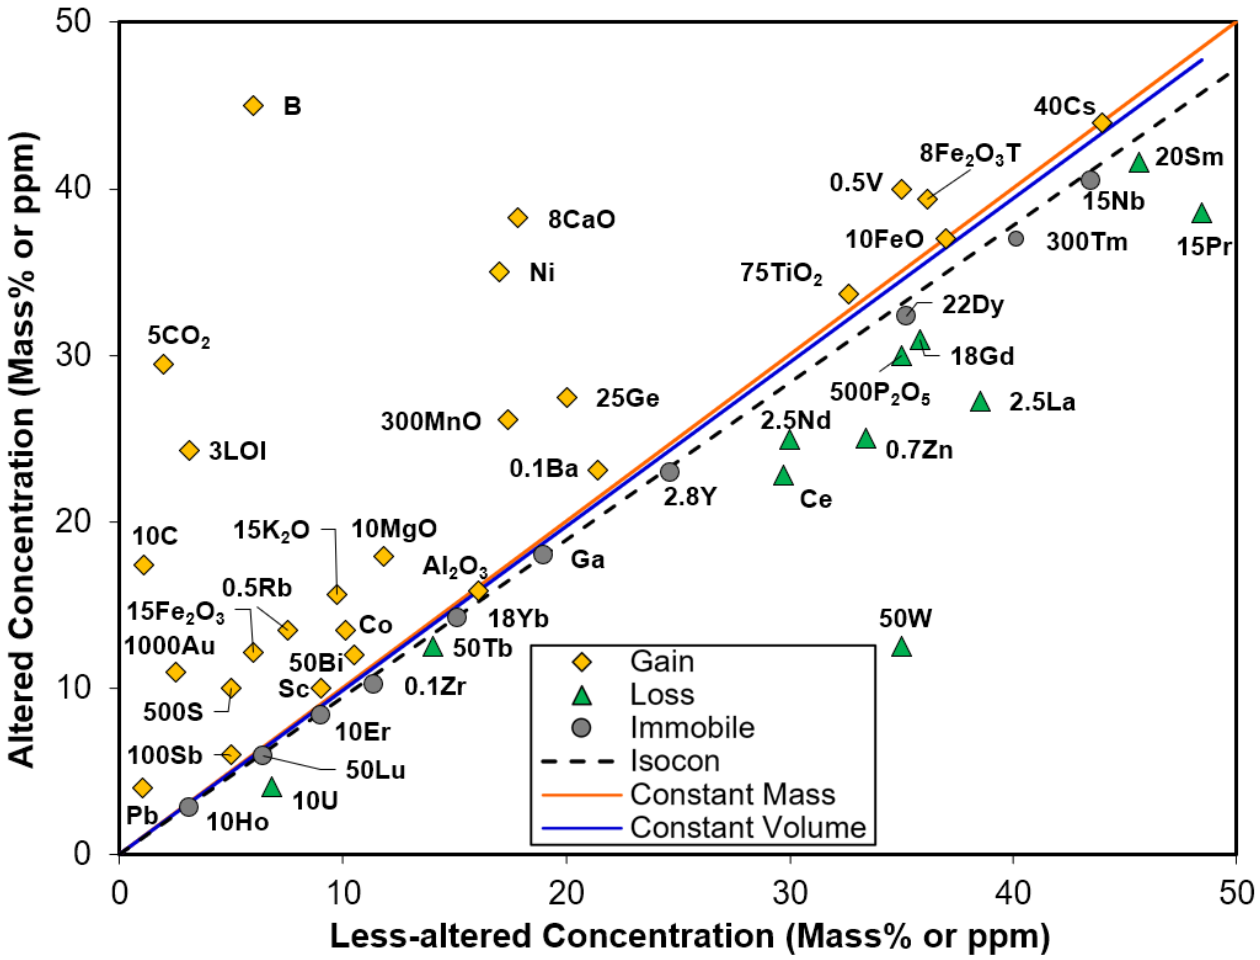

Figure 43. *Isocon diagram displaying an altered dacitic sample (T218) plotted against a representative least-altered dacitic sample (T241). This carbonate-sercite alteration zone is not associated with quartz veining or appreciable gold mineralization but has a superficial resemblance to the alteration associated with gold-bearing quartz veins. In addition to chemical species determined to be relatively immobile for this altered/least-altered pair, only chemical species that are consistently enriched or depleted, based on the study of multiple altered/less-altered pairs, are displayed. Concentrations of elements are arbitrarily scaled to avoid stacking/overlap. This is achieved by multiplying both the concentration of the chemical species in the altered sample and the concentration of the chemical species in the less-altered sample by the scale factor/multiplier shown beside each chemical species. LOI=Loss on ignition, Fe_2O_3T=Total Iron. The methods used to construct these diagrams are detailed in Section 3.2.2.*

Table 4. *Summary of chemical enrichments and depletions associated with different lithologies, alteration envelopes, and vein types located throughout the Island Gold deposit. Elements and oxides that are consistently enriched or depleted based on the examination of multiple altered/less-altered pairs (Isocon analysis; Appendix S) are displayed. The number of altered/less-altered pairs that these gains and losses were determined from are indicated in the right-most column. Gains and losses in rows labelled "All" correspond with consistent gains and losses associated with the indicated vein type(s) throughout the deposit. Gains and losses in rows labelled "Most" correspond with consistent gains and losses associated with the indicated vein type(s) throughout the deposit with the exception of one or two altered/less-altered pairs where the indicated gains/losses are not observed. If a lithology is not listed, all altered/less-altered pairs associated with the indicated vein type(s) are considered. Descriptive terms for the approximate location within the deposit where dacitic altered/less-altered pairs affected by auriferous quartz veining were taken from are included. The locations of each of the alteration envelopes described using these terms are shown in Figure 19. LOI=Loss on ignition, Fe_2O_3T=Total Iron. Methods are discussed in Sections 3.2.2, 3.2.4, and 4.2.*

	Enrichments / Gains	Depletions / Losses	Number of Altered/ Less-Altered Pairs
Dacite, East (V_1-V_2 veins)	As, Au, Bi, Co, Fe_2O_3, Fe_2O_3T, K_2O, LOI, Mo, Ni, Pb, Rb, S, Se, Te, Tl	P_2O_5, SiO_2, Sr, U	3
Dacite, West (V_1-V_2 veins)	Al_2O_3, As, Au, Bi, Co, Ge, K_2O, LOI, Rb, S, Sc, Ta, Te, V, W	Mo, Na_2O, P_2O_5, Sr	3
Dacite, Shallow (V_1-V_2 veins)	Ag, As, Au, B, C, CaO, CO2, Cr, Cs, Fe_2O_3T, Ga, K_2O, La, LOI, MnO, Nd, Ni, P_2O_5, Rb, S, Sb, Se, SiO_2, Sm, Te, Tl, U, W	Cu, Li, Na_2O, Sr	3
Dacite, Deep (V_1-V_2 veins)	Ag, As, Au, Ba, C, CO_2, Cu, Ge, Hf, K_2O, La, LOI, Mo, Pb, Rb, S, Sb, SiO_2, Te, Tl, U, W, Zn,	B, Co, Fe_2O_3T, FeO, MgO, MnO, Na_2O, Ni, Sc, TiO_2, Tm, V	2
Dacite, Centre (V_1-V_2 veins)	As, Au, B, Ba, Bi, Cr, Cs, Ge, K_2O, Li, Lu, Mo, Rb, S, Sc, SiO_2, Te, TiO_2, Tl, V, W, Yb	C, CaO, CO_2, Eu, Na_2O, Ni, Sr	2
All Dacites (V_1-V_2 veins)	As, Au, K_2O, Rb, S, Se, Te		13
Most Dacites (V_1-V_2 veins)	As, Au, Bi, K_2O, LOI, Rb, S, Se, Te, Tl, W	Na_2O, Sr	13
Dacite, Goudreau Zone (V_{GD} vein)	Ag, As, Au, Bi, Cr, Cs, Cu, Fe_2O_3, Fe_2O_3T, Ge, K_2O, Mo, Ni, Rb, S, Sb, Sc, Te, V, W, Zn	Dy, FeO, Gd, Na2O, P_2O_5, Pr, Sr	3
All Dacites (V_1-V_2 and V_{GD} veins)	As, Au, K_2O, Rb, S, Se, Te		16
Most Dacites (V_1-V_2 and V_{GD} veins)	As, Au, Bi, K_2O, Rb, S, Se, Te, Tl, W	Na_2O, Sr	16
Dacite, (Non-auriferous Sericitization/Carbonation)	Al_2O_3, Au, B, Ba, Bi, C, CaO, Co, CO_2, Cs, Fe_2O_3, Fe_2O_3T, FeO, Ge, K_2O, LOI, MgO, MnO, Ni, Pb, Rb, S, Sb, Sc, TiO_2, V	Ag, As, Ce, Gd, La, Nd, P_2O_5, Pr, Sm, Tb, Tl, U, W, Zn	2
Gabbro (V_1-V_2 Veins)	Au, B, Ba, Cs, K_2O, Li, MnO, Pb, Rb, S, Sm, Sr, Te	Bi, Ge, Na_2O, P_2O_5, Sb, Tl	3
Webb Lake Stock (V_1-V_2 Veins)	Ag, As, Au, B, Bi, C, CO_2, Cu, Fe_2O_3, Ge, K_2O, LOI, Mo, Rb, S, Se, Ta, Te, U, W	CaO, Co, Fe_2O_3T, FeO, MnO, Na_2O, Sc, SiO_2, Sm	3
Gabbro/Lamprophyre (V_3 Veins)	As, Au, B, Ba, Bi, Ce, Cr, Cs, Ga, Ge, K_2O, La, Li, Mo, Rb, Sb, Sr, V, W, Zn	Ag, C, CaO, Co, CO_2, Dy, Er, LOI, Lu, MgO, MnO, Na_2O, Ni, Pb, Se, SiO_2, Tb, Tm, Y, Yb	2
Diorite-Monzodiorite (V_3 Veins)	As, Au, CaO, FeO, Hf, Li, S, Sc, Te, W	B, Ba, C, CO_2, Cr, Cs, Cu, Fe_2O_3, Ga, K_2O, LOI, Mo, Na_2O, Ni, Pb, Rb, Sb, Se, Sr, U	2
All (V_1-V_2 veins)	Au, K_2O, Rb, S, Te		22
Most (V_1-V_2 veins)	As, Au, K_2O, Rb, S, Se, Te, W	Na_2O	22
All (V_1-V_2 and V_{GD} veins)	Au, K_2O, Rb, S, Te		19
Most (V_1-V_2 and V_{GD} veins)	As, Au, K_2O, Rb, S, Se, Te, W	Na_2O	19

Table 5. *Results of mass balance calculations based on the chemistry of dacitic samples variably altered by V_1-V_2 veining. Average concentrations of chemical species (C) for samples classified under each alteration strength grouping as well as the calculated concentration changes (ΔC) of chemical species are displayed. Concentration changes of chemical species relative to their average concentration in the least-altered samples are displayed ($\Delta C/C_{LA}$). All altered samples are altered by V_1-V_2 veins. Calculations were performed using an equation from Grant (1986) with modified variables: $\Delta C/C_{LA}$=(slope of Isocon)*(C_A/C_{LA})-1. C=Concentration, C_A=Concentration in altered sample, C_{LA}=Concentration in least-altered sample. LOI=Loss on Ignition, Fe_2O_3T=Total Iron. The following samples were used for each alteration strength grouping: Strongly-altered (T58, T72, T86, T157, T162, T188), moderately-altered (T17, T20, T73, T85, T88, T156, T186), weakly-altered (T13, T59, T117, T118, T184), least-altered (T8, T11, T65, T116, T154, T164, T183, T241).*

	Strongly-altered			Moderately-altered			Weakly-altered			Least-altered
	C	ΔC	$\Delta C/C_{LA}$	C	ΔC	$\Delta C/C_{LA}$	C	ΔC	$\Delta C/C_{LA}$	C

Table 6. *Results of mass balance calculations based on the chemistry of dacitic samples variably altered by V_{GD} veining. Average concentrations of chemical species (C) for samples classified under each alteration strength grouping as well as the calculated concentration changes (ΔC) of chemical species are displayed. Concentration changes of chemical species relative to their average concentration in the least-altered samples are displayed ($\Delta C/C_{LA}$). All altered samples are altered by V_{GD} veins. Calculations were performed using an equation from Grant (1986) with modified variables: $\Delta C/C_{LA}$=(slope of Isocon)*(C_A/C_{LA})-1. C=Concentration, C_A=Concentration in altered sample, C_{LA}=Concentration in least-altered sample. LOI=Loss on Ignition. Fe_2O_3T=Total Iron. The following samples were used for each alteration strength grouping: Strongly-altered (T105, T113), moderately-altered (T114), weakly-altered (T115), least-altered (T8, T11, T65, T116, T154, T164, T183, T241).*

	Strongly-altered			Moderately-altered			Weakly-altered			Least-altered

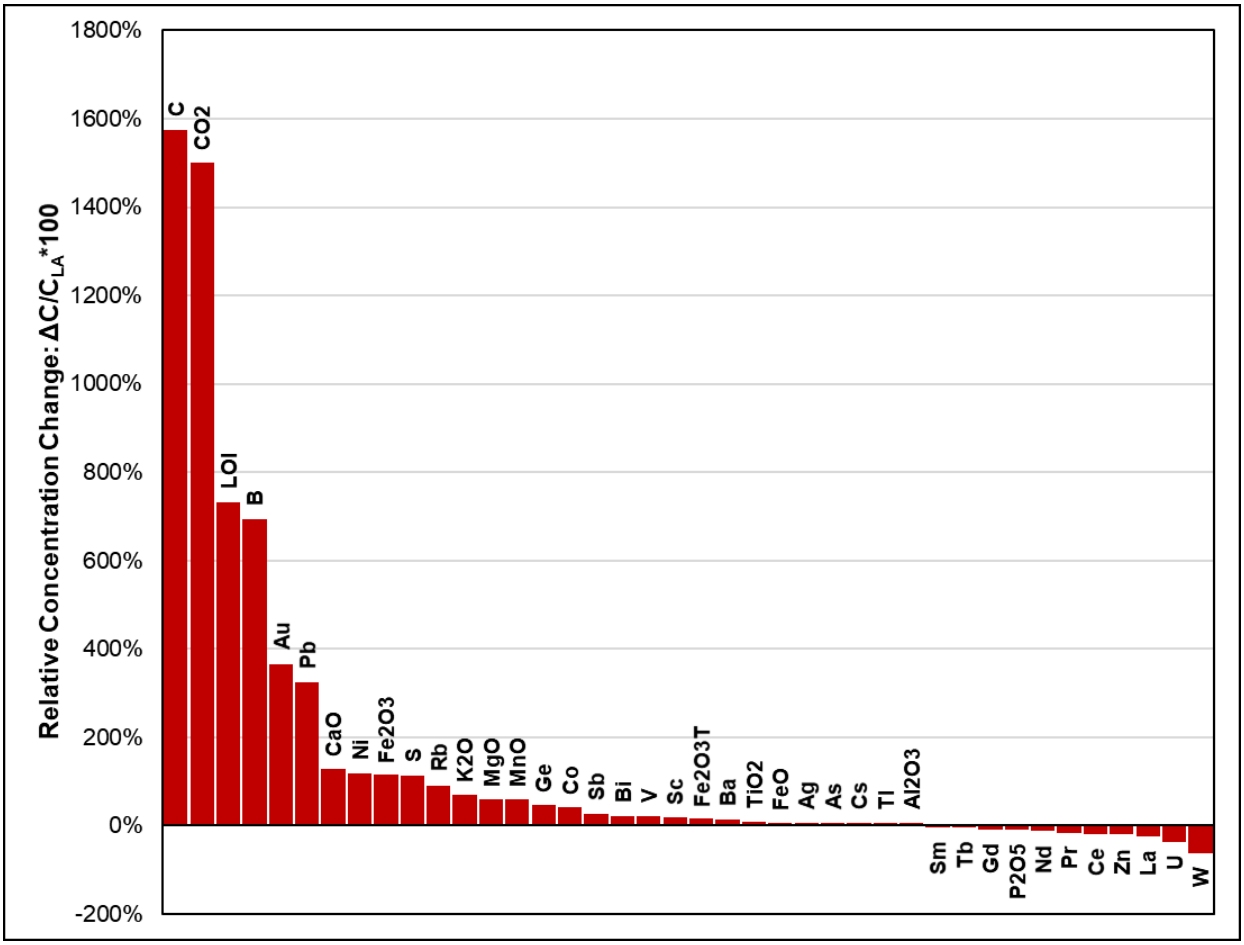

Figure 44. *Relative concentration changes of chemical species between an altered dacitic sample (T218) within a non-economic, carbonate-sericite alteration zone and a representative least-altered dacitic sample (T241). Chemical gains/losses are expressed as a percentage relative to the least-altered sample. Only chemical species that are consistently enriched or depleted, based on the study of multiple altered/least-altered pairs, are displayed. Calculations were performed using the following equation from Grant (1986) with modified variables:* $\Delta C/C_{LA}$*=(slope of isocon)*(*C_A/C_{LA}*)-1. The slope of the Isocon in Figure 43 was used. C=Concentration,* C_A*=Concentration in altered sample,* C_{LA}*=Concentration in least-altered sample. LOI=Loss on Ignition,* Fe_2O_3T*=Total Iron.*

Table 7. *Concentrations of chemical species in an altered dacitic sample (T218) within a non-economic carbonate-sericite alteration zone and a least-altered dacitic sample (T241). Concentration changes of chemical species between the least-altered and altered samples are also displayed. Relative concentration changes are expressed as a percentage relative to the least-altered sample. Only chemical species that are consistently enriched or depleted, based on the study of multiple altered/least-altered pairs, are displayed. Calculations were performed using the following equation from Grant (1986) with modified variables: $\Delta C/C_{LA}$=(slope of isocon)*(C_A/C_{LA})-1. The slope of the Isocon in Figure 43 was used. C=Concentration, C_A=Concentration in altered sample, C_{LA}=Concentration in least-altered sample. LOI=Loss on Ignition, Fe_2O_3T=Total Iron.*

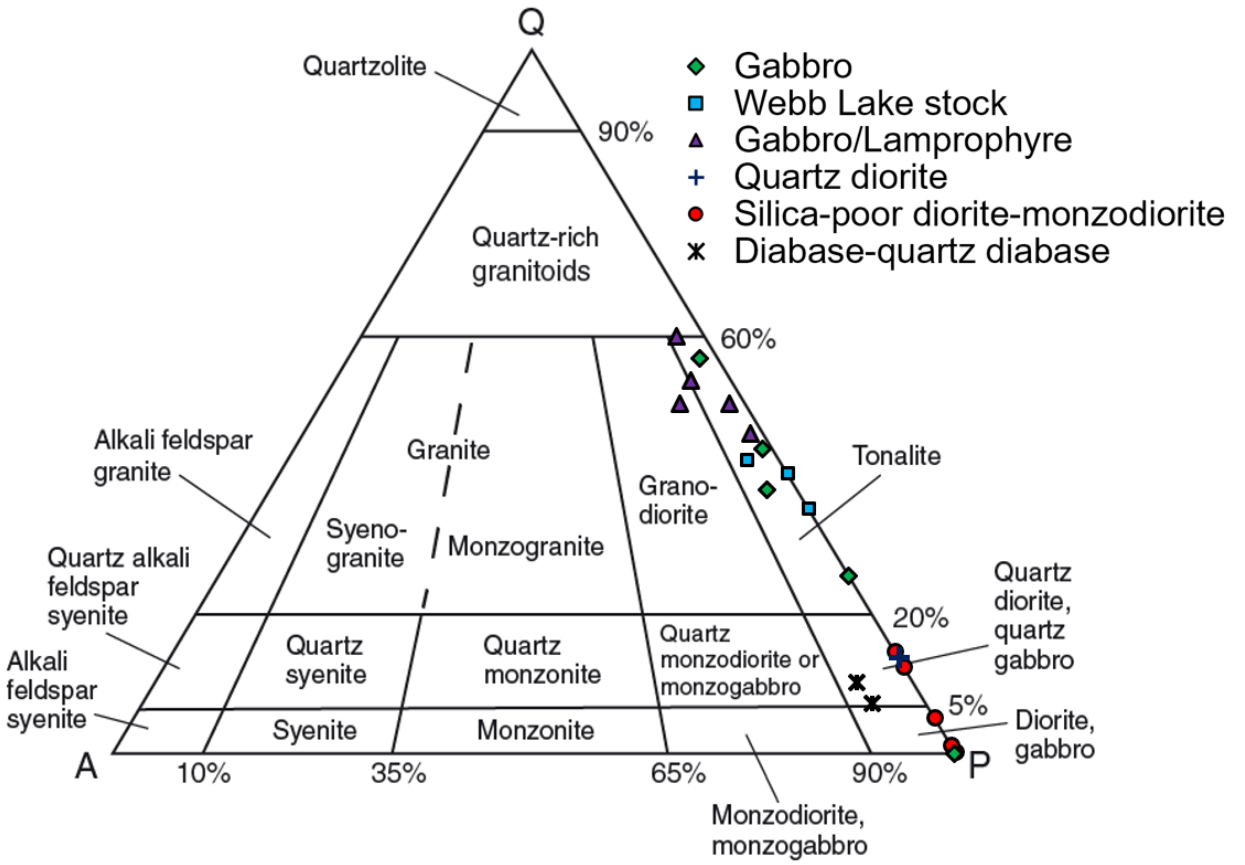

Figure 45. *Least-altered and weakly-altered intrusive samples (Section 4.2) plotted on a Quartz-Alkali Feldspar-Plagioclase (QAP) ternary diagram. Modal mineralogy determined using the standard CIPW Norm calculations for gabbro, gabbro/lamprophyre, and diabase–quartz diabase. The CIPW Norm modification that includes biotite is used for all other lithologies because substantial primary biotite was observed in these samples. Calculations were conducted using GCDkit (Janoušek et al., 2006) using the methods outlined in Hutchison (1975). This diagram is modified from Streckeisen (1976a).*

Figure 46A–D. *Least-altered and weakly-altered samples (Section 4.2) of the various intrusive lithologies at the Island Gold deposit plotted on classification diagrams. This caption applies to the figures on the previous two pages. A) A TAS diagram for intrusive lithologies. Modified from Middlemost (1994). B) R_1-R_2 multicationic plot modified from De La Roche et al. (1980) and Janoušek (2018). C) A P-Q multicationic plot modified from Debon and Le Fort (1983) and Janoušek (2018). to=Tonalite, gd=Granodiorite, ad=Adamellite, gr=Granite, dq=Quartz Diorite, mzdq=Quartz Monzodiorite, mzq=Quartz Monzonite, sq=Quartz Syenite, go=Gabbro, mzgo=Monzogabbro, mz=Monzonite, s=Syenite. D) A modified Nb/Y-Zr/Ti diagram modified from Pearce (1996) and Janoušek (2018). This diagram is originally from Winchester and Floyd (1977) and was later revised in Pearce (1996). This diagram is designed to classify extrusive igneous rocks based on ratios of relatively immobile element ratios. It has been modified for intrusive rocks by replacing extrusive rocks with their respective intrusive equivalent.*

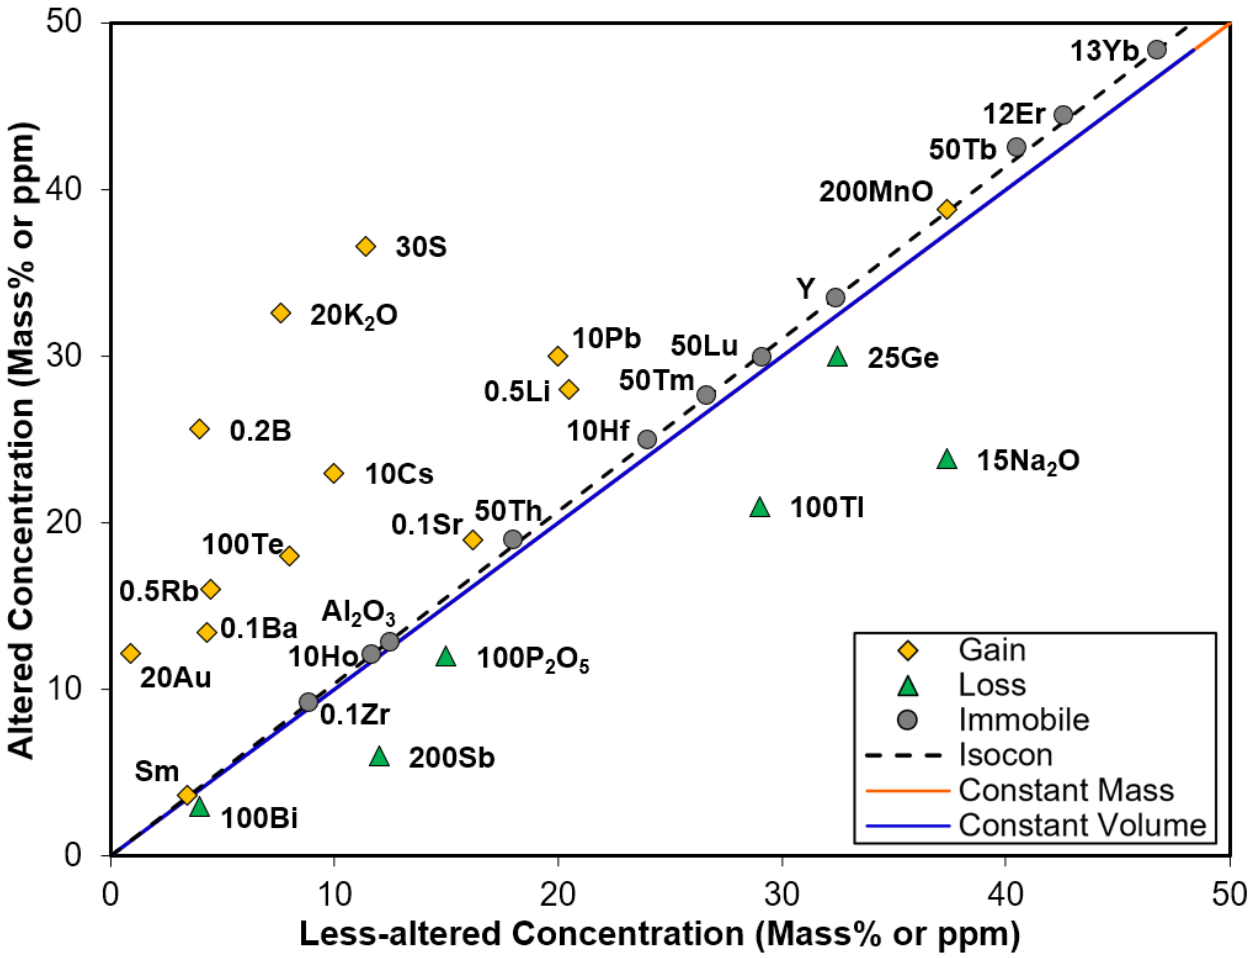

Figure 47. *Isocon diagram displaying an altered gabbroic sample (T141) plotted against a less-altered gabbroic sample (T139) from the same alteration envelope. This alteration envelope is associated with V_1-V_2 auriferous quartz veining. In addition to chemical species determined to be relatively immobile for this altered/less-altered pair, only chemical species that are consistently enriched or depleted, based on the study of multiple altered/less-altered pairs, are displayed. Concentrations of elements are arbitrarily scaled to avoid stacking/overlap. This is achieved by multiplying both the concentration of the chemical species in the altered sample and the concentration of the chemical species in the less-altered sample by the scale factor/multiplier shown beside each chemical species. LOI=Loss on Ignition, Fe_2O_3T=Total Iron. The methods used to construct these diagrams are detailed in Section 3.2.2.*

Table 8. *Results of mass balance calculations based on the chemistry of samples of gabbro altered by V_1-V_2 veining. Average concentrations of chemical species (C) for samples classified under each alteration strength grouping as well as the calculated concentration changes (ΔC) of chemical species are displayed. Concentration changes of chemical species relative to their average concentration in the least-altered samples are displayed ($\Delta C/C_{LA}$). Calculations were performed using the following equation from Grant (1986) with modified variables: $\Delta C/C_{LA}$=(slope of Isocon)*(C_A/C_{LA})-1. C=Concentration, C_A=Concentration in altered sample, C_{LA}=Concentration in least-altered sample. LOI=Loss on Ignition, Fe_2O_3T=Total Iron. The following samples were used for each alteration strength grouping: Strongly-altered (T142), moderately-altered (T140, T141), weakly-altered (T139), least-altered (T14, T80, T89, T182, T200).*

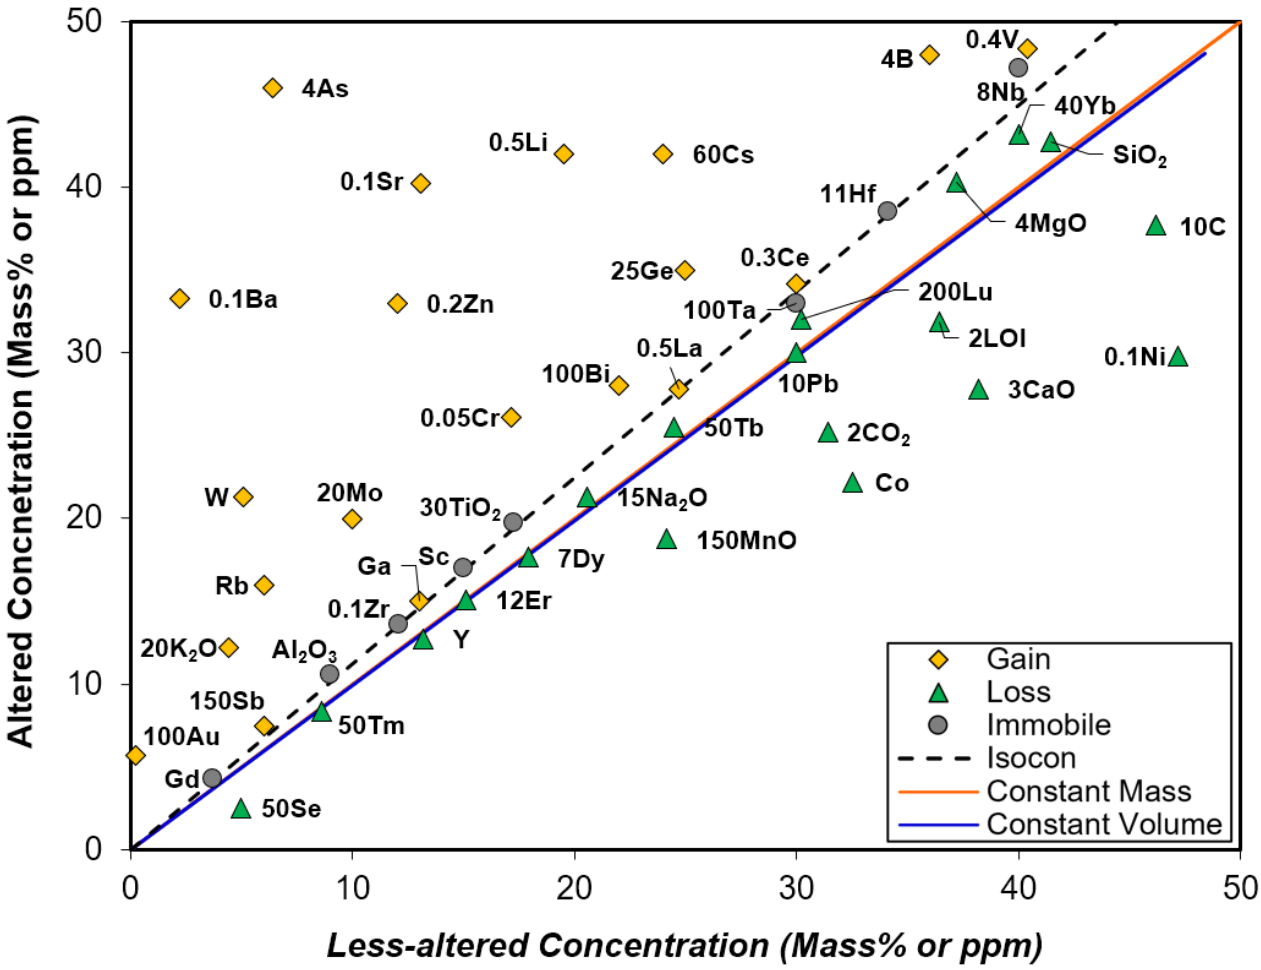

Figure 50. *Isocon diagram displaying an altered sample of gabbro/lamprophyre (T213) plotted against a least-altered sample of gabbro/lamprophyre (T239). The altered sample has been altered by an adjacent V_3 quartz vein. Concentrations of elements are arbitrarily scaled to avoid stacking/overlap. This is achieved by multiplying both the concentration of the chemical species in the altered sample and the concentration of the chemical species in the least-altered sample by the scale factor/multiplier shown beside each chemical species. In addition to chemical species determined to be relatively immobile for this altered/least-altered pair, only chemical species that are consistently enriched or depleted, based on the study of multiple altered/less-altered pairs, are displayed. LOI=Loss on ignition, Fe_2O_3T=Total Iron. The methods used to construct these diagrams are detailed in Section 3.2.2.*

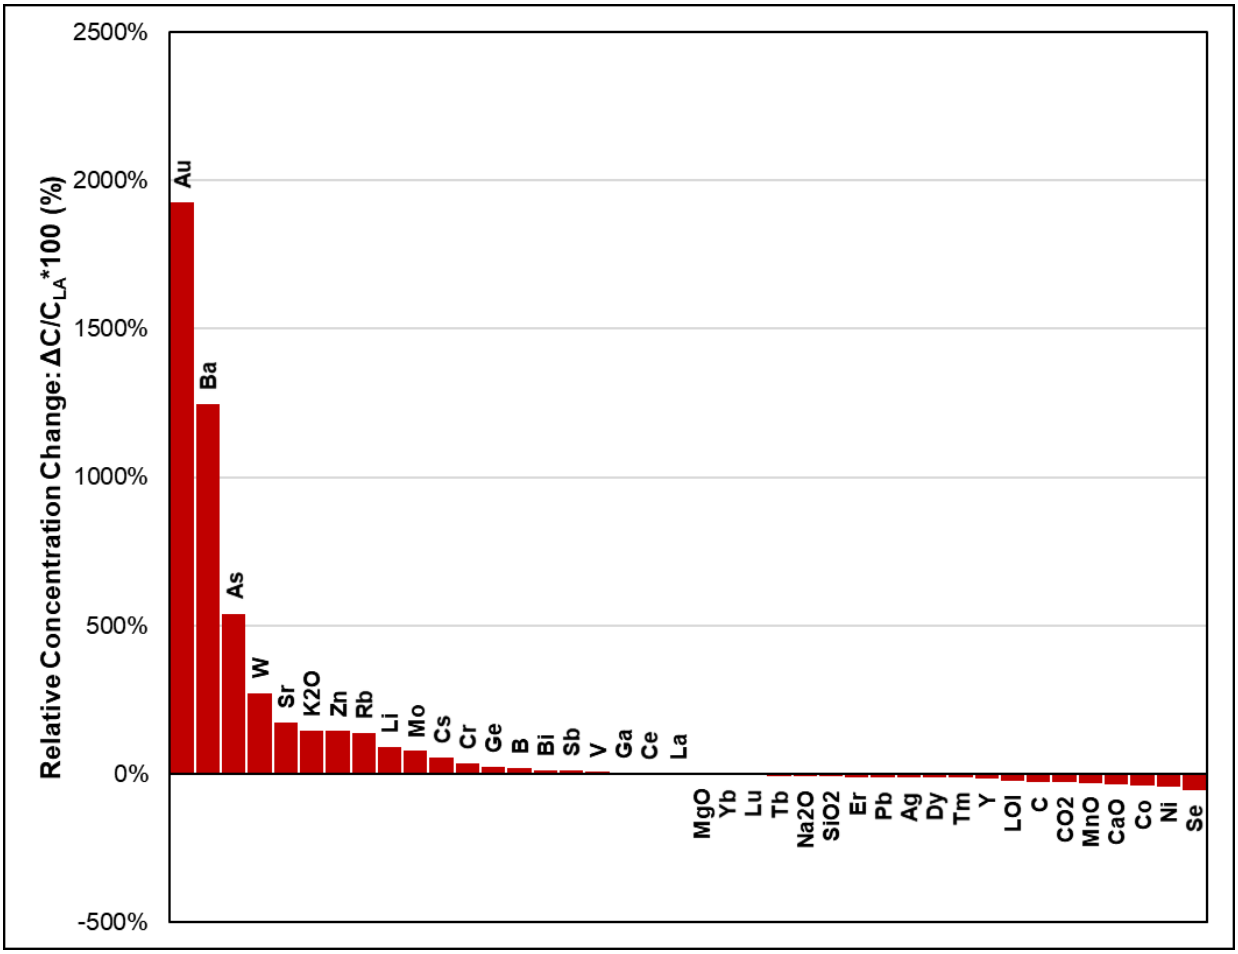

Figure 51. *Relative concentration changes of chemical species between a representative least-altered sample of gabbro/lamprophyre (T239) and a sample of gabbro/lamprophyre (T213) altered by a V_3 quartz vein. Chemical gains/losses are expressed as a percentage relative to the least-altered sample. Only chemical species that are consistently enriched or depleted, based on the study of multiple altered/least-altered pairs, are displayed. Calculations were performed using the following equation from Grant (1986) with modified variables: $\Delta C/C_{LA}$=(slope of isocon)*(C_A/C_{LA})-1. The slope of the Isocon in Figure 50 was used. C=Concentration, C_A=Concentration in altered sample, C_{LA}=Concentration in least-altered sample. LOI=Loss on Ignition. Fe_2O_3T=Total Iron.*

Table 10. *Concentration and relative concentration changes of chemical species between a sample of gabbro/lamprophyre altered by a V_3 vein and a least-altered sample of gabbro/lamprophyre. Relative concentration changes are expressed as a percentage relative to the least-altered sample. Only chemical species that are consistently enriched or depleted, based on the study of multiple altered/least-altered pairs, are displayed. Calculations were performed using the following equation from Grant (1986) with modified variables: $\Delta C/C_{LA}=(\text{slope of isocon})*(C_A/C_{LA})-1$. The slope of the Isocon in Figure 50 was used. C=Concentration, C_A=Concentration in altered sample, C_{LA}=Concentration in least-altered sample. LOI=Loss on Ignition. Fe_2O_3T=Total Iron.*

4.3 Mineral compositions

Six thin sections were selected for electron probe microanalysis of key minerals (biotite, white mica, chlorite, epidote, plagioclase, and carbonates). These thin sections consisted of altered and least-altered pairs from a dacite-hosted (T157 and T154), a Webb Lake stock-hosted (T195 and T192), and a gabbro-hosted (T141 and T139) ore zone. The least-altered gabbro sample (T139) is actually classified as a weakly-altered sample (Section 4.2.4.2) but, for simplicity, is referred to as a least-altered sample in this section. Altered samples of these lithologies are altered by V_1-V_2 auriferous veins. All electron microprobe results are located in Appendix H.

4.3.1 Biotite

Compositions of biotite from the gabbro and Webb Lake stock are summarized in Table 12 and plotted on a biotite classification diagram in Figure 54. Compositions of biotite in altered and least-altered gabbro samples are similar and plot close to the centre of the biotite field on the Annite-Phlogopite-Eastonite-Siderophyllite (APSE) diagram (Figure 54A). However, biotite in the altered sample generally has slightly lower Fe/(Fe+Mg) than biotite in the least-altered sample (Figure 54A). Biotite from the least-altered Webb Lake stock sample have similar compositions to biotite in the gabbro (Figure 54B). Biotite from altered samples of the Webb Lake stock have significantly lower Fe/(Fe+Mg) values (Figure 54B), more fluorine (Table 12) and less potassium (Table 12) than biotite in least-altered samples of the Webb Lake stock. These compositional differences affirm the presence of both primary biotite and alteration-derived biotite in the Webb Lake stock.

4.3.2 Chlorite

Compositions of chlorite from the dacite, Webb Lake stock, and gabbro are summarized in Table 13 and plotted on a chlorite classification diagram in Figure 55. Chlorite within individual samples exhibit minimal compositional variation (Table 13). Most measured compositions are consistent with the chlorite end-member ripidolite (Figure 55A–C). Chlorite in altered samples of the dacite and Webb Lake stock tends to be more enriched in silica and magnesium when compared to chlorite in least-altered equivalents (Table 13). Chlorite in least-altered and altered samples of the gabbro is compositionally similar (Table 13).

4.3.3 White mica

Compositions of white mica are summarized in Table 14 and plotted on a ternary classification diagram in Figure 56. The altered gabbroic sample did not contain any white mica. White Mica within individual samples exhibits minimal compositional variation (Table 14) and all plot in the muscovite phengite fields (Figure 56). Similarly, when comparing white mica in altered and least-altered equivalents, the composition of the mica does not change substantially. Slight increases in magnesium and titanium as well as decreases in calcium and iron are noted in altered samples when compared to equivalent least-altered samples (Table 14). White mica in both altered and least-altered dacitic samples is consistent with muscovite (Figure 56A). White mica in the least-altered gabbroic sample is phengite (Figure 56B). White mica in the altered and least-altered samples of the Webb Lake stock both cluster on the phengite-muscovite boundary with analyses plotting in both fields. White mica in the least-altered sample is mainly consistent with phengite while white mica in the altered sample is mostly muscovite (Figure 56C). Considering that there are distinct compositional groupings of white mica in the dacite and Webb Lake stock, this supports the hypothesis that there are two generations of muscovite with the later related to alteration associated with V_1-V_2 veining.

4.3.4 Plagioclase

Compositions of plagioclase are summarized in Table 15 and plotted on a Anorthite-Albite-Orthoclase (An-Ab-Or) feldspar classification diagram in Figure 57. With the exception of the altered gabbroic sample, analyses of plagioclase show substantial variation in concentrations of SiO_2, Al_2O_3, Na_2O, and CaO. Plagioclase compositions from in all samples are mostly consistent with oligoclase and andesine (Figure 57A–C). Plagioclase in the altered dacitic sample is mainly oligoclase while plagioclase in the least-altered equivalent is comparatively sodium and silica-poor and is mainly andesine (Figure 57A). Plagioclase in the least-altered gabbro has a wide range of compositions ranging from oligoclase to andesine while plagioclase in the altered sample clusters exclusively in the oligoclase field of the An-Ab-Or diagram (Figure 57B). Plagioclase in the altered sample of the Webb Lake stock is mainly consistent with andesine while plagioclase in the least-altered sample of the Webb Lake stock is more sodium and silica-rich and ranges from oligoclase to albite (Figure 57C).

4.3.5 Carbonate minerals

Compositions of carbonate minerals are summarized in Table 16 and plotted on a ternary classification diagram in Figure 58. Some carbonates within the same samples were subdivided into different groups because they have distinctly different compositions. Carbonate minerals in the least-altered dacitic sample cluster near the calcite end-member on the Magnesite-Siderite-Calcite (MSC) ternary diagram (Figure 58A). Carbonates in the altered dacitic sample were subdivided into two groups. Carbonate B and has significantly higher concentrations of magnesium and iron than Carbonate A. Carbonate A is calcite and Carbonate B is magnesio-ferro-calcite (Figure 58A).

Within each of the samples of gabbro, carbonates compositions show little chemical variation (Table 16) and are both consistent with calcite (Figure 58B). Analyses of carbonates in the least-altered sample of the Webb Lake stock are compositionally similar and are consistent with calcite (Figure 58C). Carbonates in the altered samples of the Webb Lake stock display significant compositional variation and as a result have been subdivided into four groups (Carbonate C–F; Figure 58C). Calcium content increases moving sequentially from Carbonate C to Carbonate F. Carbonate C and D cluster farthest from the calcite end-member with Carbonate D being closer than Carbonate C. Carbonates C and D are magnesio-ferro-calcites. Carbonate E and F are calcites. Carbonate F has lower average silica and aluminum and has slightly higher average iron and magnesium than Carbonate E (Table 16A).

Table 12A, B. *Summary of microprobe analyses of biotite measured in mass percent. A) Average concentrations of chemical species based on analyses of biotite in each sample. Figure 58A–C. *Carbonate mineral compositions from altered and least-altered equivalents plotted on Magnesite-Siderite-Calcite (MSC) ternary diagrams. The location of the intermediate carbonates, dolomite and ankerite, are also included. Mole proportions of Mg, Fe, and Ca (Appendix H) are used to plot on this diagram. Total iron is assumed to be all ferrous iron.*

4.4 Gold indicators and grade distribution

Economic gold grades at the Island Gold deposit are located in V_{GD} and V_1-V_2 veins and their associated alteration envelopes. Lithologies that can host economic gold grades if they coincide with an auriferous zone include dacite, iron formation, gabbro, and the Webb Lake stock. However, iron formation was not observed to coincide with an area of V_{GD} or V_1-V_2 veining so the results outlined below may not apply to this lithology. Alteration minerals associated with auriferous quartz veining at the Island Gold deposit mainly include biotite, Ca-Mg-Fe carbonates, chlorite (ripidolite), plagioclase, quartz, sulphides (pyrite ± pyrrhotite ± chalcopyrite), and white mica (muscovite ± phengite; Section 4.1, 4.3).

Gold grade is divided into three groups in this thesis: high-grade (> 4 g/t Au), low-grade (1–4 g/t Au), and waste rock (< 1 g/t Au; Figure 59). High-grade samples are restricted to auriferous quartz veins and a portion of the strongly-altered zone directly adjacent to these veins. All high-grade samples contain macroscopically visible V_{GD} or V_1-V_2 veins/veinlets, quartz flooding and/or silicification. These samples also typically have the highest proportion of alteration-derived minerals.

Low-grade samples are present in auriferous quartz veins, as well as the entire strongly-altered zone (Figure 59). Grades > 1 g/t are typically not found in the moderately-altered zone. Most low-grade samples contained macroscopically visible V_{GD} or V_1-V_2 veins/veinlets, quartz flooding and/or silicification. All low-grade samples that did not have these features were samples of strongly-altered rocks that contained greater than 3 vol% sulphide minerals.

All samples of waste material (< 1 g/t Au) did not have macroscopically visible V_{GD} or V_1-V_2 veins/veinlets, quartz flooding and/or silicification. In addition, these samples had less than 3 vol% sulphide minerals. Waste rock samples also typically have lower proportions of alteration minerals than both high-grade and low-grade samples (Section 4.1). The moderately-altered zone contains mostly 0.1–1 g/t Au whereas samples taken from the weak or least-altered zones have concentrations of gold usually > 0.1 g/t (Figure 59).

In summary, macroscopically visible V_{GD} or V_1-V_2 veins/veinlets, quartz flooding and/or silicification are the most reliable indicators for economic gold grades at the Island Gold deposit. Sulphide minerals are also useful and easily recognizable mineral indicators that can be used to differentiate between potential low-grade material and waste that do not contain macroscopically visible V_{GD} or V_1-V_2 veins/veinlets, quartz flooding and/or silicification. Proportions of other

alteration minerals can be used to help discern which zone of an alteration envelope a sample is located in (Section 4.1; Figure 16, Figure 17, Figure 20), which in turn can be used to estimate gold grade. However, proportions of these minerals alone do not correspond reliably enough with gold content to be used to differentiate between cut-off grades. Subtle increases in the proportions of chlorite and carbonate minerals relative to unaltered rock mark the outer edge of alteration envelopes associated with gold-bearing quartz veins. However, the weakly-altered outer margins of these alteration envelopes are challenging to identify because chlorite and carbonates are also metamorphic minerals.

Increasing strength of alteration due to V_{GD} or V_1-V_2 veining in pre-gold mineralization lithologies or increasing proportions of these vein types in a given sample typically corresponds with increasing gold content. Outside of auriferous quartz veins themselves, the most reliable geochemical vectors/indicators for alteration/gold mineralization that are consistent for all lithologies are K_2O, Rb, S, and Te enrichment as well as Na_2O depletion (Table 4). Other common geochemical enrichments include As, Se, and W (Table 4). Copper concentration is consistently enriched in Webb Lake stock-hosted ore zones (Table 4). As a result, even trace amounts of chalcopyrite or other copper-bearing minerals may be a useful indicator for economic gold grades within this lithology.

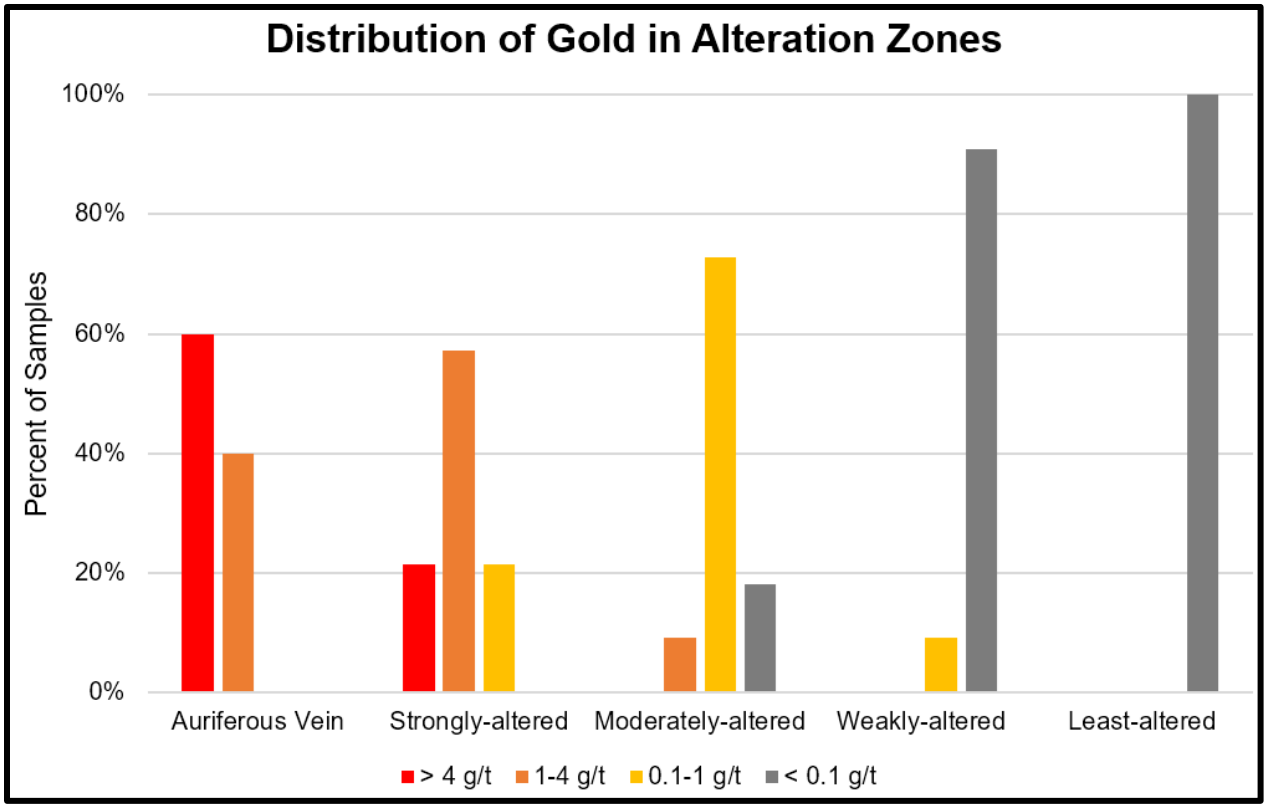

Figure 59. *Samples of dacite, gabbro, the Webb Lake stock, as well as V_{GD} and V_1-V_2 auriferous quartz veins are subdivided into five groupings: Auriferous vein, strongly-altered, moderately-altered, weakly-altered, and least-altered. This histogram displays the proportion of samples, within each of these groupings, which fall into each of the gold-grade intervals outlined in the legend. Gold grade groupings used in this thesis are as follows: > 4 g/t is considered high grade, 1-4 g/t is considered low grade, and < 1.0 g/t is considered waste.*

4.5 Sulphur isotopes

Results of sulphur isotope analyses from the University of Maryland are summarized in this section and in Figure 60. A complete list of all sulphur isotope data is presented in Appendix K and Appendix L. Two analyses of sulphur in pyrite-rich iron formations are similar (-1.33‰ and -0.46‰) while one value deviates significantly (19.60‰). All of their $\Delta^{33}S$ and $\Delta^{36}S$ values are consistent with $\Delta^{33}S$ values ranging from -0.508‰ to -0.551‰ (Figure 60), and $\Delta^{36}S$ values ranging from 0.7‰ to 0.8‰ (Appendix L).

Sulphur in V_1 and V_2 quartz veins and their associated alteration envelopes display fairly consistent $\delta^{34}S$ and $\Delta^{33}S$ values. $\delta^{34}S$ values range from 1.22‰ to 2.92‰, and $\Delta^{33}S$ values range from -0.057‰ to -0.033‰. These $\delta^{34}S$ and $\Delta^{33}S$ value ranges include samples of both pyrite and pyrrhotite from ore zones hosted by each of the three major host lithologies (dacite, tonalite–trondhjemite and gabbro). $\Delta^{36}S$ values range from 0.06‰ to -0.05‰, excluding one pyrite sample from a gabbro-hosted alteration envelope which has an anomalously high value of 0.8‰.

Pyrite from a V_{GD} vein has a $\delta^{34}S$ value of 2.00‰ and a $\Delta^{36}S$ value of -0.05‰. These are consistent with the ranges of these values found in sulphides from auriferous zones throughout the deposit. However, the $\Delta^{33}S$ value of this sample is 0.143‰ and this differs from the samples taken from auriferous quartz vein corridors zones associated with V_1 and V_2 vein types even if analytical uncertainty is considered.

Pyrite from a silica-poor diorite–monzodiorite intrusive that commonly parallels auriferous quartz vein corridors at this deposit has a $\delta^{34}S$ value of 1.92‰ which is within the range of values found in sulphide minerals from auriferous quartz veins throughout the deposit. However, this is not the case for the $\Delta^{33}S$ value of 0.806‰ and the $\Delta^{36}S$ value of -0.1‰ which both differ significantly from these ranges.

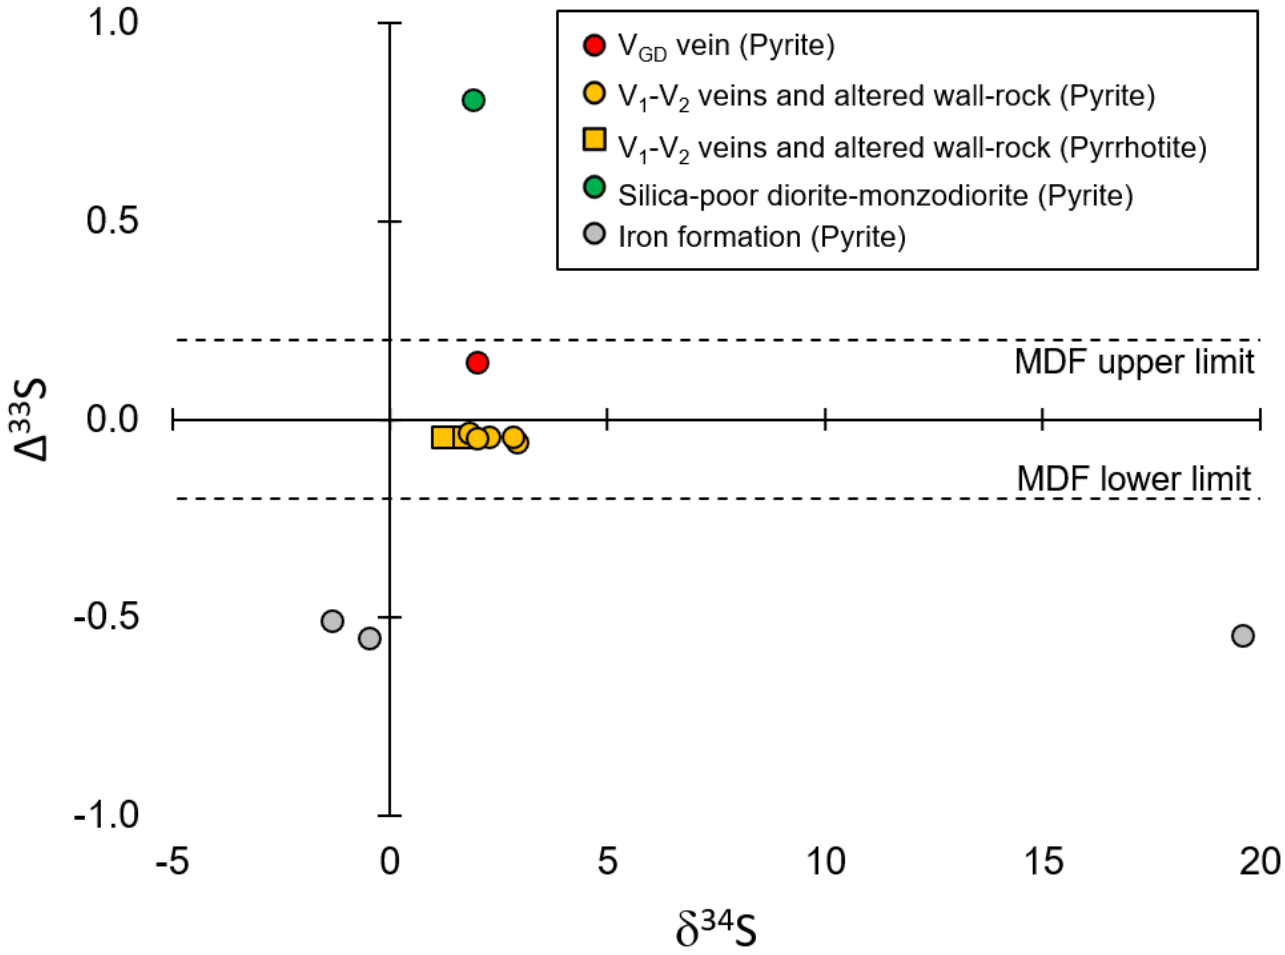

Figure 60. *$\delta^{34}S$ vs $\Delta^{33}S$ plot of samples from auriferous quartz vein corridors and various other sulphide-bearing lithologies at the Island Gold deposit. Sulphides include both pyrrhotite and pyrite. Dashed lines indicate approximate upper and lower limits for $\Delta^{33}S$ values that can be produced exclusively by MDF processes (Farquhar and Wing, 2003). Sulphides that plot outside of these points show evidence of MIF. Sulphides that plot within these bounds may have been produced through via MDF processes alone or are a combination of MDF and MIF sulphur.*

4.6 Laser ablation inductively coupled mass spectrometry (LA-ICP-MS)

U-Pb zircon geochronology was performed on zircons from an intensely hydrothermally-altered dacitic sample and a least-altered equivalent nearby. The alteration envelope, from which this altered sample was taken, centred around V_1-V_2 auriferous quartz veining. As is common in ore zones related to V_1-V_2 veins, some V_3 non-auriferous quartz veins and tourmaline were also present in this alteration envelope. The least-altered sample was taken from outside or at the outer margin of the alteration envelope. Zircons in both samples exhibit distinct oscillatory and sector zoning in cathodoluminescence (CL) images (Figure 61). Zircons in the least-altered sample were larger (typically <300 μm) and subhedral–euhedral (Figure 61A). Zircons in the altered sample are smaller (typically <200 μm), anhedral–subhedral, and often fractured (Figure 61B–C). Occasionally, some of these zircons have an anomalous mottled/uniform/homogeneous appearance in CL images where the oscillatory and sector zoning (Figure 61B–D) is indistinct. These anomalous areas of indistinct zonation are present as portions of zircons, rims, or affect entire zircon grains (Figure 61B–D). Centres of zircons and edges were targeted for U-Pb analysis on zircons from both the altered and least-altered sample. The spot locations where each analysis was conducted are displayed in Figure 70 (Appendix B). Geochronological results are summarized in Appendix M, Figure 62, and Figure 63.

47 analyses of zircons from the least-altered sample yielded a weighted mean $^{207}Pb/^{206}Pb$ age of 2735 ± 8 Ma (MSWD = 1.04; Figure 62). This age is interpreted to represent the crystallization age of the dacite.

Excluding spot locations located on the anomalous rims and grains discussed above, 37 spots on zircons from the altered sample yielded a weighted mean $^{207}Pb/^{206}Pb$ age of 2738 ± 9 Ma (MSWD = 0.53, Figure 63D), which is within uncertainty of zircon from the least-altered sample and is interpreted to represent the crystallization age of the dacite. Spot locations located on the mottled CL portions of zircons in the altered sample yielded Proterozoic ages that range from approximately *c.* 975 to 1499 Ma (Figure 63B). Some reverse discordance is observed in least-altered samples, altered samples, and standards (Figure 62A, Figure 63A-C, Figure 69A) and may be related to down-hole fractionation. Similarly, many of the Proterozoic ages plot above concordia (Figure 63B) and therefore the results should be treated with caution. Nonetheless, there is a significant Proterozoic population at *c.* 1.1–1.2 Ga (Figure 63A, B).

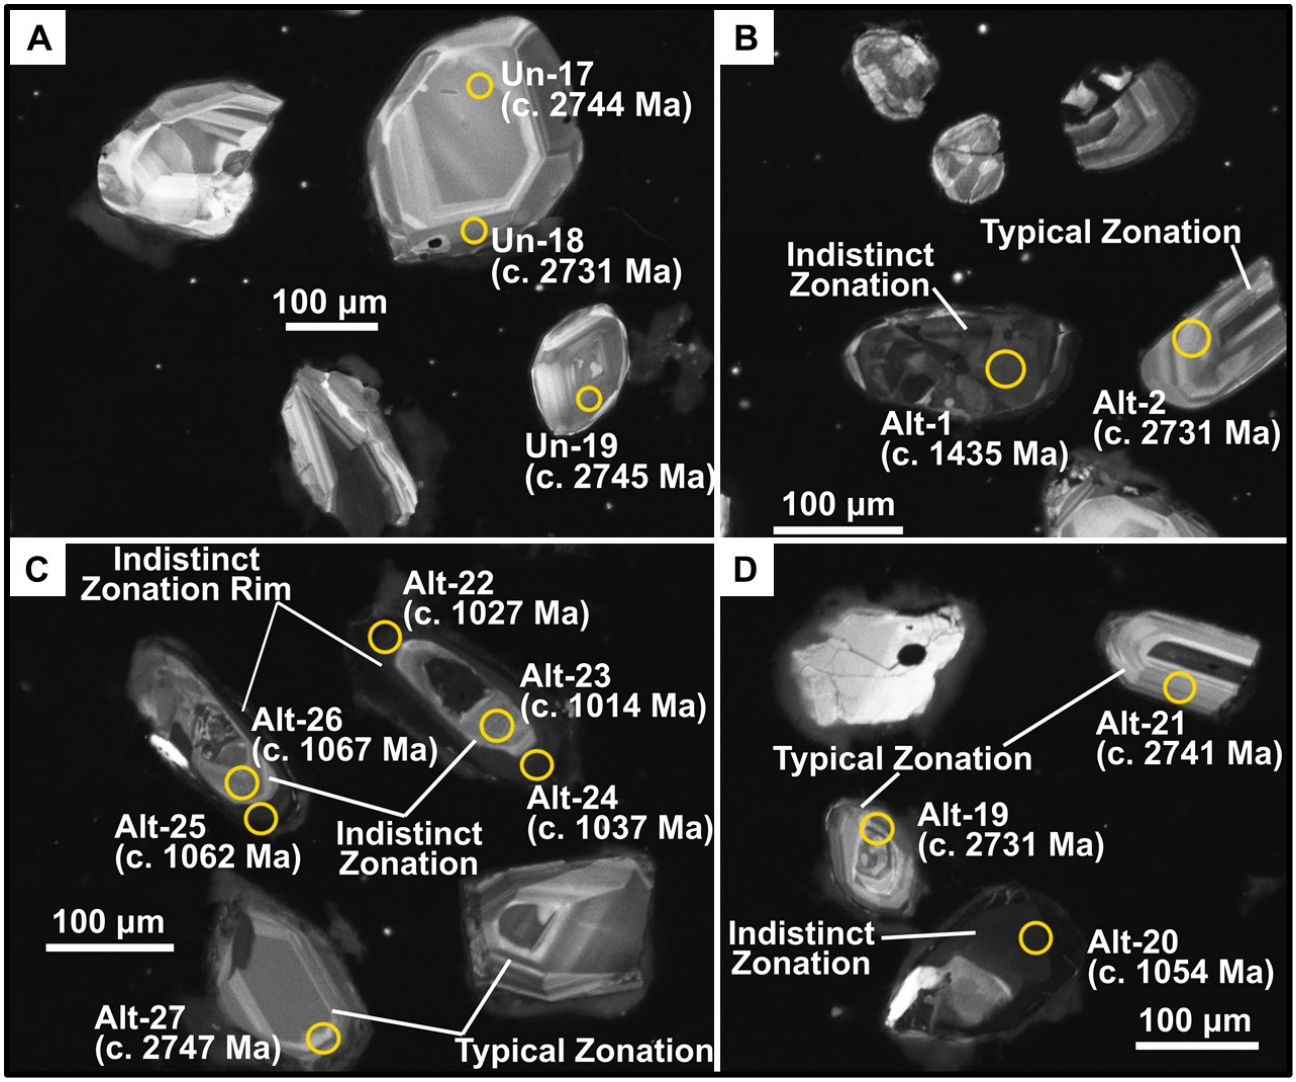

Figure 61. *Cathodoluminescent photomicrographs of zircons from an altered dacite and a least-altered equivalent. Spot locations and $^{207}Pb/^{206}Pb$ ages are displayed when applicable. A) Large, euhedral–subhedral zircons from the least-altered sample displaying typical distinct zonation. B) Subhedral–anhedral zircons from the altered sample. Some zircons display indistinct zonation while others display typical distinct zonation. C) Subhedral zircons from the altered sample. Some zircons display indistinctly zoned cores and rims while others display typical distinct zonation. Spot locations on zircons and corresponding approximate ages are displayed when applicable. D) Anhedral–subhedral zircons from the altered sample. Some zircons display distinct zonation while others display typical distinct zonation.*

5.0 Discussion

5.1 Protoliths and genetic history

The interpreted protoliths of each of the major lithologies at the Island Gold deposit based on field relationships, petrology and geochemistry are discussed below for each rock type. The interpreted geological significance of each rock type is also discussed when applicable.

5.1.1 Dacitic volcanic rocks (T2, V2, I2)

This lithology is interpreted to be volcanic in origin due to the presence of tuffs (often with lapilli and/or bombs), flows, pyroclastic breccias, and compositionally equivalent hypabyssal intrusive units (Figure 10). The bulk composition of these volcanic rocks are broadly dacitic based on the TAS diagram and the R_1-R_2 diagram (Figure 38A, B). Considering that silica is generally considered mobile during metamorphism (e.g. Ague, 1991) these diagrams may not be appropriate if silica was substantially mobilized in least-altered samples. The immobile elements are suggestive of an andesite–basaltic andesite or a dacite/rhyolite protolith (Figure 39A, B). However, the presence of a large proportion of primary minerals in many least-altered samples of this lithology (e.g. Figure 14D) suggest that the standard classification of volcanic rocks using the TAS diagram can still be used with reasonable certainty.

Archean volcanic rocks in the Superior Province are thought to be generated by volcanism related to either subduction-related processes (e.g. Wyman et al., 2002; Percival et al., 2012) or non-subduction, plume/delamination-related tectonic processes (e.g. Bédard, 2006; Bédard and Harris, 2014). Therefore, the dacitic volcanic rocks at the Island Gold deposit are not diagnostic of either tectonic process.

5.1.2 Iron formation (IF)

The iron formation at the Island Gold deposit is consistent with Algoma-type iron formations (e.g. Gross, 1980) as indicated by its limited spatial extent, Archean age, and association with volcanic rocks in a greenstone belt. This agrees with previous studies which have also classified the Michipicoten iron formation as an Algoma-type iron formation (Sage, 1994). These iron formations are thought to have formed due to periodic oxidation of iron in seawater resulting in the precipitation of iron oxides followed by periods of regular, iron-oxide-poor sedimentation. Biological and non-biological mechanisms that caused the oxidation of iron

are still debated (Bekker et al., 2010). As discussed in Section 5.7, the sulphides in these banded iron formations are believed to have a biogenic signature, which suggests that early organisms may have had a role in the genesis of these iron formations.

5.1.3 Gabbro (I3G)

This mafic intrusive rock contains few primary minerals and mostly greenschist-facies assemblages (Section 4.1.10). With the exception of the Q-P plot (Figure 46C), both mobile and immobile element plots consistently indicate that the protolith is a gabbro (Figure 46). The chondrite-normalized REE profile of this lithology is flat (Figure 40B) which is characteristic of transitional mid oceanic ridge basalts (Schilling et al., 1983) or low-K (tholeiitic) island arc rocks (e.g. Gill, 1981). Given the absence of unambiguous Archean ophiolites (Warren, 2011) and the significant volume of dacitic volcanic rocks at the Island Gold deposit and surrounding area, a mid ocean ridge origin is unlikely and it is more probable that this lithology is related to an island arc setting.

5.1.4 Webb Lake stock: Tonalite–trondhjemite (I1JM)

With the exception of chlorite replacing primary biotite, the least-altered and weakly-altered samples of the Webb Lake stock appear to be composed mostly of primary minerals. These samples plot in the tonalite field of the QAP diagram (Figure 27) and the trondhjemite field of the Anorthite-Albite-Orthoclase diagram (Figure 48). The amount of ferromagnesian minerals in most samples is > 10 vol%, which is consistent with a tonalite (Barker, 1979). However, some samples, particularly those farther from the margins of the Webb Lake stock contain < 10 vol% ferromagnesian minerals and are therefore are considered trondhjemite. In summary, the Webb Lake stock ranges from tonalitic to trondhjemitic in composition at the Island Gold deposit.

The REE patterns of least-altered samples of the Webb Lake stock, including the lack of Eu anomalies, are typical of Archean tonalite-trondhjemite-granodiorites (TTGs) (Moyen and Martin, 2012). The genesis of Archean TTGs is still widely debated and both subduction and non-subduction genetic models are considered (Moyen and Martin, 2012). Therefore, this rock type is not diagnostic of a particular geodynamic setting.

5.1.5 Gabbro/Lamprophyre (I2H)

This lithology has a similar appearance to the gabbro discussed in Section 5.1.3. Key mineralogical, textural, and chemical differences that can be used to differentiate between these lithologies are summarized in Appendix A. This lithology contains few primary minerals and mostly greenschist-facies assemblages (Section 4.1.10). Based on the chemical composition and metamorphic mineral assemblage, interpreted primary minerals likely consisted mainly of Ca-rich plagioclase, hornblende, pyroxene, and potentially olivine.

Mobile and immobile element plots are consistent with gabbro or diorite classifications (Figure 46). This lithology may be a gabbro or silica-poor gabbro based on the low concentrations of SiO_2. Yet, the high proportion of volatiles (LOI of 7.5–18.1 wt%), high average Cr (405 ppm), Ni (317 ppm), Th (6 ppm), and Na_2O (1.6 wt%) content, low average Si content (43.5 wt%), and occurrence as dykes suggest that a low-K lamprophyre is another potential alternative (Streckeisen et al., 2002). Based on the relatively high average Na_2O (1.6 wt%) and CaO (10.6 wt%), but low K_2O (0.2 wt%), this sodic-calcic lamprophyre likely had low proportions of primary potassium-rich minerals (e.g. biotite or potassium feldspar). Therefore, it would be classified as spessartite which is dominated by hornblende and plagioclase (Streckeisen et al., 2002). However, lamprophyres are typically enriched in potassium (Streckeisen et al., 2002), so a gabbroic classification is still plausible.

This REE pattern of least-altered samples of this lithology is similar to that of ocean island basalts (Wilson, 1989), and continental flood basalts (Hooper and Hawkesworth, 1993). It is also similar to the REE pattern of lamprophyres (e.g. Zhilong et al., 2002) including those in the Superior Province (e.g. Stern and Hanson, 1992). Therefore, the protolith of this lithology is interpreted to be either a lamprophyre (spessartite) or a gabbro. Neither of these lithologies are restricted to a certain tectonic setting.

5.1.6 Quartz diorite

This lithology appears less affected by metamorphism than many other lithologies at the Island Gold deposit and is classified as a quartz diorite based on mineralogy (Figure 27). Mobile and immobile element chemical classification plots suggest a quartz monzonite, quartz syenite, and syenite classification (Figure 46). However, the extremely low potassium content (0.05 wt% K_2O) and absence of primary potassium feldspar discount these potential classifications. The

quartz-carbonate veins observed in the quartz diorite xenoliths but not the silica-poor diorite–monzodiorite (Figure 32A) likely formed due to competency differences between the two lithologies. The quartz diorite is brittle relative to the silica-poor diorite–monzodiorite and as a result, the quartz diorite fractured rather than deforming when stress was applied. Dioritic rocks are present in a wide range of tectonic environments and as a result are not diagnostic of a specific geological setting.

5.1.7 Silica-poor diorite–monzodiorite (I2M)

The silica-poor diorite–monzodiorite may have a similar appearance to the gabbro and gabbro/lamprophyre discussed in Sections 5.1.3 and 5.1.5. Key mineralogical, textural, and chemical differences that can be used to differentiate between these lithologies are summarized in Appendix A. The variability in the appearance and chemical composition of the silica-poor diorite–monzodiorite may be caused by variable magmatic assimilation of earlier lithologies (e.g. Figure 32A). This unit is classified as a diorite based on its current mineralogical composition (Figure 27). Primary potassium feldspars may have been present in greater proportions in the protolith but have since been replaced by biotite and white mica. As a result, a monzodiorite protolith could also be possible. Mobile element and immobile element plots suggest a wide range of classifications that broadly agree with diorite or monzodiorite. These include monzodiorite, monzogabbro, foid-bearing gabbro, foid-bearing monzogabbro, monzonite, diorite, and gabbro-diorite (Figure 46A–D). The presence of primary oligoclase and lack of significant proportions of ferromagnesian minerals is inconsistent with a gabbro. The low silica content (37.9 to 45.9 wt%) suggests the potential for primary feldspathoids that may have been replaced during metamorphism and alteration. However, no feldspathoid minerals were observed, so a silica-poor diorite–monzodiorite is an appropriate name for the likely protolith.

This intrusion may be related to other silica-undersaturated intrusions in the area, such as the Herman Lake nepheline syenite intrusive complex that was dated at 2671 +17/-10 Ma (Corfu and Sage, 1992). This age is similar to that obtained from this silica-poor diorite–monzodiorite at the Island Gold deposit (2672.2 ± 3.5 Ma; Jellicoe, 2019). Low degrees of partial melting of the alkali-rich, subcontinental lithospheric mantle lherzolite due to lithospheric extension can generate silica-undersaturated magmas equivalent to a nepheline syenite (Laporte et al., 2014).

5.1.8 Diabase–quartz diabase (I3DD)

This lithology is classified as a gabbro–quartz gabbro based on the QAP diagram (Figure 27). This intrusion is typically fine-grained (Figure 36A), particularly at its margins, which is consistent with a diabase–quartz diabase and supports the classification by Sage (1994). Mobile and immobile element classification plots suggest gabbro, alkali gabbro, gabbro-diorite, and quartz diorite classifications (Figure 46A–D) which broadly support this diabase/gabbro classification. This lithology may correspond with the Matachewan dyke swarm which occurred at 2473 +16/-9 (Heaman, 1997) and has been previously documented in this area (e.g. Jellicoe, 2019). Average concentrations of SiO_2, alkalis ($Na_2O + K_2O$), Fe_2O_3T, MgO, Ni, and Cr in the diabase–quartz diabase fall within the concentration ranges of Matachewan dykes in Ciborowski et al. (2015). Chondrite-normalized rare-earth element patterns of diabase–quartz diabase samples from this thesis (Figure 40G) are consistent with those of those of known Matachewan dykes (Ciborowski et al., 2015) suggesting the diabase–quartz diabase at the Island Gold deposit is part of the Matachewan dyke swarm. These rare-earth element patterns are similar to those of enriched mid-ocean ridge basalts (MORBs), ocean island basalts (OIBs), and continental flood basalts (Schilling et al., 1983; Wilson, 1989; Hooper and Hawkesworth, 1993). However, the setting of these dykes is not characteristic of MORBs or OIBs. Flood basalts, on the other hand, have been linked to the Matachewan Large Igneous Province which includes the Matachewan dyke swarm (Ciborowski et al., 2015). The Matachewan dykes are believed to be related to a mantle plume that resulted in rifting and continental break-up (Ciborowski et al., 2015).

5.2 Greenschist-facies metamorphism

The abundance of typical greenschist-facies metamorphic minerals such as chlorite, actinolite, and epidote at the Island Gold deposit is consistent with regional greenschist-facies metamorphism which has previously been interpreted in the Michipicoten greenstone belt (e.g. Sage, 1994). The margins of the Michipicoten greenstone belt reached amphibolite-facies conditions (Ayres, 1978) but at the Island Gold deposit, the vast majority of samples do not show evidence for metamorphism exceeding greenschist-facies conditions. The sporadic, late, randomly-oriented chloritoid and, in rare cases garnet (often associated with chloritoid; Figure 65), likely formed at the end or after regional deformation. This is because these minerals are typically not preferentially-oriented. These minerals may have formed during the later stages of

regional metamorphism because these minerals often overprint other metamorphic minerals. However, the distribution of rocks bearing these minerals and their metamorphic significance is not clear. Alternatively, the gabbro and chloritoid may be related to an alteration event unrelated to regional metamorphism.

Metamorphism continued after the formation of the gold-bearing quartz veins but appears to have had only a minor effect on the alteration assemblages generated as a result of gold mineralization. Greenschist-facies assemblages are easily observed in the gabbro and gabbro/lamprophyre and are less obvious in the quartz diorite and silica-poor diorite–monzodiorite. The quartz diorite and silica-poor diorite-monzodiorite may have been emplaced after peak metamorphism. The diabase–quartz diabase intrusions have been affected the least by metamorphism and only display minor growth of metamorphic minerals, typically at the margins of primary minerals. Therefore, the intrusion of the diabase–quartz diabase is interpreted to post-date regional greenschist-facies metamorphism, which occurred during D2 deformation (Jellicoe, 2019).

5.3 Auriferous quartz vein-related alteration

5.3.1 V_{GD} and V_1-V_2 vein-related alteration of dacitic volcanic rocks

V_{GD} and V_1-V_2 veining resulted in the growth of the same alteration minerals. Besides the larger proportion of white mica and chlorite and lower proportions of quartz and feldspar in samples altered by V_{GD} veins compared to samples altered by V_1-V_2 veins, the alteration mineral assemblages associated with these vein types are very similar (Figure 16). These differences in the proportion of minerals may be attributed to protolith compositional differences or differences in the extent of alteration. Besides minerals in samples altered by V_1-V_2 veins typically exhibiting more deformation, samples altered by V_1-V_2 veins and those altered by V_{GD} veins are also texturally equivalent. The alteration envelopes associated with V_1-V_2 veins tend to be larger (Section 4.1.2.1). This is interpreted to be due to the shearing associated with V_1-V_2 veining creating more structural conduits which can accommodate the movement of hydrothermal fluids further outward from the central vein. Furthermore, with the exception of LOI, Se, and Tl, all chemical species that were typically enriched (As, Au, Bi, K_2O, Rb, S, Te and W) and depleted (Na_2O and Sr) as a result of alteration associated with V_1-V_2 veining were also enriched and depleted as a result of alteration related to V_{GD} veining (Table 4). Based on mass balance

calculations, these chemical species also generally had the greatest magnitude of enrichment/depletion relative their concentrations in least-altered samples (Table 5, Table 6). The consistency of the mineralogy, textures, and chemistry of samples altered by V_{GD} veins and samples altered by V_1-V_2 veins suggests that these veins were produced under comparable conditions by a hydrothermal fluid of similar composition. The same mineralogical and chemical vectors can be used when exploring for gold mineralization related to V_{GD} and V_1-V_2 vein types.

The addition of K_2O during alteration resulted in the growth of muscovite in altered samples and the addition of sulphur generated Fe-sulphide minerals at the expense of primary and metamorphic Fe-bearing minerals. This is consistent with the lower Fe content in chlorite in altered samples (Figure 55A; Table 13). This is also supported by pyrite clusters near pre-existing iron-bearing minerals (e.g. Figure 18).

There is not a continuous increase in the proportion of carbonate minerals with increasing alteration because there are generally more carbonate minerals in the moderately-altered zone than either the strongly-altered or weakly-altered zones (Figure 16A, B). This is because strongly-altered rocks are directly proximal to quartz veins. Silicification is a significant alteration type adjacent to quartz veins and results in less carbonate minerals adjacent to these veins compared to the moderately-altered zone. As a result, despite carbonates being major alteration minerals, CO_2 (a major constituent of carbonate minerals) does not consistently correlate with increasing alteration (Table 4) because strongly-altered samples often contain less CO_2 than moderately-altered samples.

Plagioclase in the least-altered sample is andesine while plagioclase in the altered sample ranges from oligoclase to andesine (Figure 57A). This suggests that alteration resulted in either the replacement of Ca with Na in relict primary andesine producing oligoclase or the formation of some alteration-derived oligoclase. In addition, the proportion of plagioclase in altered samples is significantly lower than in least-altered samples indicating that alteration related to V_1-V_2 veining resulted in the significant breakdown of primary plagioclase. As a result, Na_2O depletion due to alteration is probably a result of the breakdown of primary andesine and the removal of sodium by the hydrothermal fluid.

Significant alteration-derived quartz is generally restricted to the strongly-altered zones and hence SiO_2 is not consistently enriched due to alteration across entire alteration envelopes (Table 4). Given the enrichment in Au, As, Bi, Rb, Se, Te, and Tl (Table 4), these elements were

likely associated with the Au-bearing fluid(s), however, these elements were not introduced in large enough quantities to result in the formation of visible minerals that contain these chemical species as a major structural component (e.g. tellurides). Similarly, the fluid likely resulted in the removal of Sr which was not present in a significant amount prior to alteration to form any minerals with Sr as a major structural component.

5.3.1.1 Deposit-scale variations in V_1-V_2 vein-related alteration

The mineralogy and chemistry of dacitic samples taken from alteration envelopes associated with V_1-V_2 veining in the dacitic volcanic rocks are consistent throughout the deposit (Sections 4.1.2.3.1 and 4.2.2.2.1) with some minor differences. These minor anomalous gains and losses of a variety of chemical species were observed in each alteration envelope. These are attributed to limited sampling of individual alteration envelopes resulting in apparent gains and losses due to non-alteration-related sample heterogeneities.

Increased silicification is noted in the strongly-altered sample from the deepest alteration envelope studied (Figure 68; Appendix B). This tentatively suggests that silicification may be a more dominant alteration type in deeper ore zones associated with V_1-V_2 veining. The strongly-altered sample from a V_1-V_2 ore zone located approximately at the centre of current mine workings (~500m depth; Figure 19) has more white mica (44 vol%) when compared to the white mica content in the average strongly-altered sample (33 vol%). This is probably the result of V_3 veining and/or a protolith more enriched in aluminum. The low amount of carbonate minerals noted in strongly-altered samples from both the central (<1 vol%) and deep ore zones (1 vol%) (Figure 19), is attributed to these samples being taken from the portion of the strongly-altered zone directly adjacent to V_1-V_2 veining. Low proportions of carbonates are often present in the portion of the strongly-altered zone that is proximal to auriferous quartz veining. The moderately-altered zone and the distal portion of the strongly-altered zone typically have more carbonate minerals. Besides these minor differences in mineral proportions discussed above, the overall signature of the alteration in dacite-hosted alteration envelopes related to auriferous quartz veining remains consistent with varying distance parallel to the GLDZ and elevation.

5.3.2 V_1-V_2 vein-related alteration of gabbro

Gains of K_2O due to alteration associated with V_1-V_2 veining in gabbro-hosted alteration envelopes at the Island Gold deposit is due to the increased amount of biotite in alteration zones (Figure 17A). Higher sulphide mineral proportions in altered zones (Figure 17A) results from the introduction of S. Similar to the dacite, there is not a continuous increase in the proportion of carbonate minerals with increasing alteration. In this case, fewer carbonate minerals were observed in the moderately-altered sample compared to the strongly-altered and weakly-altered samples (Figure 17A). As a result, despite calcite being a major alteration mineral, increasing CO_2 and CaO content do not consistently correspond with increasing alteration (Table 4).

The restricted range of plagioclase compositions (oligoclase) in the altered sample relative to the large range of plagioclase compositions (oligoclase to andesine) in the less-altered sample (Figure 57B) indicates that plagioclase generated via metamorphism was replaced by oligoclase during alteration related to V_1-V_2 veining. Plagioclase modes also increase in altered samples. Na_2O depletion in altered samples (Figure 47) is due to the breakdown of sodic, metamorphic-derived oligoclase (almost albite; Figure 57B) and sodium-bearing amphibole.

Alteration-derived quartz is restricted to the strongly-altered zone and hence SiO_2 is not consistently enriched due to alteration across entire alteration envelopes (Table 4). Gold is present mainly as free gold in the quartz veins and altered wall rock and is interpreted to have been introduced by the fluid that generated the V_1-V_2 veins. The larger proportion of tourmaline in altered samples is due to mass gains in B (Figure 47). This may be because the post-V_1-V_2 fluid that caused the formation of tourmaline utilized pre-existing structural conduits including the shear zones where V_1-V_2 veining occurs. As a result, there is generally a positive correlation with tourmaline content and alteration intensity because alteration intensity increases when moving towards the centre of the shear zone.

Additionally, the auriferous hydrothermal fluid was likely enriched in Ba, Cs, Li, MnO, Pb, Rb, Sm, Sr, and Te resulting in the addition of these chemical species to altered samples (Table 4). The fluid likely removed Bi, Ge, P_2O_5, Sb, and Tl (Table 4). Unlike the dacitic volcanic lithology, only one alteration envelope hosted gabbro was studied and it is unclear how representative this single transect of a gabbro-hosted V_1–V_2 vein-related alteration envelope is for the entire deposit.

5.3.3 V_1-V_2 vein-related alteration of the Webb Lake stock

Unlike the dacite and gabbro, evidence of K_2O influx due to V_1-V_2 vein-related alteration (Figure 49) resulted in significant growth of both white mica and biotite in the Webb Lake stock. Carbonate mineral growth is attributed to gains of C and CO_2 (Figure 49) while sulphide mineral formation results in consistent S enrichment in altered samples (Table 4). The mass loss of FeO and simultaneous mass gain of ferric iron due to alteration (Figure 49) suggests the conversion of ferrous iron to ferric iron and this indicates that the gold-bearing fluid was relatively oxidizing. There is also a loss of total iron but this is typically negligible relative to the more significant gains of Fe_2O_3 and losses of FeO (e.g. Figure 49). Increasing concentrations of sulphide minerals in altered samples (Table 4) indicates that the gold-bearing fluid was also sulphur-bearing. The spatial association of alteration-derived sulphide minerals with iron-bearing minerals such as biotite and chlorite indicates that iron was sourced from these minerals for sulphide mineral growth. This is supported by lower concentrations of Fe in biotite (Table 12) and chlorite (Table 13) in altered samples. Na_2O depletion due to alteration is likely due to the breakdown of sodic plagioclase (albite and oligoclase) in altered samples (Figure 57C).

Similar to gabbro and dacite-hosted alteration envelopes, alteration-derived quartz is restricted to the strongly-altered zone and hence SiO_2 is not enriched due to alteration (Table 4). Similar to dacite and gabbro-hosted ore zones, gold is present mainly as free gold in the quartz veins and altered wall rock and is interpreted to have been introduced by the fluid that generated the V_1-V_2 veins. Presence of trace chalcopyrite, particularly in strongly-altered samples, explains the enrichment in Cu (Table 4). Breakdown of primary and metamorphic calcium-bearing minerals such as epidote and hornblende and removal of CaO by the hydrothermal fluid accounts for the loss of CaO (Table 4). The larger amount of tourmaline typically observed in altered samples can be attributed to an influx of B (Table 4). However, the B-rich fluid that produced the tourmaline post-dates V_1-V_2 veins and the same reasons for tourmaline enrichment as discussed in Section 5.3.2 also apply here.

Additionally, the hydrothermal fluid was likely enriched in Ag, As, Bi, Ge, Mo, Rb, Se, Ta, Te, U, and W resulting in the addition of these elements to altered samples (Figure 49). The fluid likely resulted in the removal of Co, MnO, Sc, SiO_2, and Sm resulting in losses of these elements due to alteration (Table 4). However, only one alteration envelope hosted by the Webb Lake stock was studied and it is unclear if these results can be extrapolated to the entire deposit.

5.4 Comparison of auriferous alteration within different lithologies

Alteration related to V_1-V_2 veining at the Island Gold deposit results in the significant and consistent enrichment of Au, K_2O, Rb, S, and Te in all altered/less-altered pairs studied, regardless of their protolith (Table 4; Section 4.2). With the exception of a single dacitic altered/less-altered pair, Na_2O depletion also consistently occurs due to V_1-V_2 veining (Table 4). The consistent enrichment and depletion of these elements suggests that alteration envelopes associated with V_1-V_2 veins throughout the deposit were all generated by the same fluid.

Alteration minerals associated with V_1-V_2 auriferous quartz veining mainly consist of biotite, Ca-Mg-Fe carbonates, chlorite (ripidolite), plagioclase, quartz, sulphides (pyrite ± pyrrhotite ± chalcopyrite), and white mica (muscovite ± phengite) (Section 4.1 and 4.3). The mineralogical changes between each zone and key mineralogical relationships that help define alteration zones in each pre-gold mineralization lithology are summarized in Figure 20. White mica is the dominant potassic mica in alteration envelopes hosted by the dacite and the Webb Lake stock (Figure 16A–C; Figure 17B). This is interpreted to be due to the simultaneous addition of potassium and the breakdown of primary plagioclase thereby providing the chemical components necessary for the growth of white mica (mainly K, Al, Si, and O). White mica is an insignificant alteration mineral in gabbro-hosted alteration envelopes (Figure 17A) when compared to dacite and Webb Lake stock-hosted alteration envelopes (Figure 16A–C; Figure 17B). Instead, biotite is the dominant potassic mineral and is likely the result of gabbro containing less Al and more Fe and Mg than the dacite and Webb Lake stock (Table 17). Significant growth of plagioclase due to alteration exclusively occurs in the gabbro (Section 4.1.4.3). Biotite is also a minor alteration mineral in the Webb Lake stock (Figure 17B), perhaps suggesting that the conversion of plagioclase to white mica was not as pervasive as in the dacite and, as a result, some alteration-derived biotite formed. Chlorite that is clearly alteration-derived was not identified in Webb Lake stock-hosted alteration envelopes but, based on slight differences in the chemistry of chlorite in altered and least-altered samples (Section 4.3.2), it may be present in minor proportions.

Carbonates in altered samples of gabbro are almost exclusively calcite (Figure 58B) whereas carbonates in altered dacitic and Webb Lake stock samples are a combination of calcite and Ca-Mg-Fe carbonates (Figure 58A, C). This suggests that calcite forms preferentially when the lithology contains significant CaO (as is the case with the gabbro; Table 17). Besides these

differences in mineralogy, which are likely due to differences in protolith composition, the alteration mineral assemblages in V_1-V_2 alteration envelopes hosted by the dacite, gabbro, and Webb Lake stock are relatively consistent.

V_{GD} veins were generated as a result of an earlier event as indicated by structural (Jellicoe, 2019) and isotopic evidence (Section 5.7). The alteration related to V_{GD} veins was studied through the examination of one dacite-hosted alteration envelope. The mineral assemblage is consistent to that observed in dacite-hosted alteration envelopes associated with V_1-V_2 veins (Figure 16). Similarly, the same consistent and significant enrichments and depletions of chemical species observed as a result of alteration of dacites by V_1-V_2 veins also occur as a result of alteration related to V_{GD} veins (Table 4). Although V_{GD} veins are a result of an earlier auriferous veining event, the mineralogical and chemical signature of the alteration is almost identical to that of V_1-V_2 veins. It is therefore extrapolated that gabbro or Webb Lake stock-hosted alteration envelopes associated with V_{GD} veins would have the same mineralogical and chemical signature as those associated with V_1-V_2 veins. This reaffirms that the same geochemical and mineralogical vectors towards V_1-V_2 auriferous zones can be employed when exploring for V_{GD} auriferous zones.

The gabbro/lamprophyre and silica-poor diorite–monzodiorite post-date and cross-cut the V_1-V_2 veins (e.g. Figure 34C). Multiple samples of the gabbro/lamprophyre and silica-poor diorite–monzodiorite were taken from intrusions that were located directly adjacent or near V_1-V_2 auriferous veining. The lack of substantial enrichment of these samples in Au, K_2O, Rb and S further supports that V_{GD} and V_1-V_2-related alteration did not affect these lithologies. Similarly, the absence of notable alteration and key alteration minerals further affirms this interpretation.

5.5 Comparison with other orogenic gold deposits

Many aspects of the mineralogical and chemical signature associated with gold mineralization at the Island Gold deposit are commonly featured in other orogenic gold deposits throughout the world. These aspects include the presence of biotite, carbonates, chlorite, plagioclase, sericite, and sulphides in the auriferous alteration assemblage. Additional features commonly include chemical enrichments of As, Au, K, S, Te, and W as a result of auriferous quartz veining (Groves et al., 1998). This supports the interpretation that the Island Gold deposit is an orogenic gold deposit (e.g. Adam et al., 2017).

The large fault systems east of the Kapuskasing Structural Zone (KSZ) that host major orogenic gold deposits have been correlated with the Goudreau Lake Deformation Zone (GLDZ) which hosts the Island Gold deposit (Leclair et al., 1993). Studies of a number of gold deposits east of the KSZ near Timmins (Hoyle Pond, Dome), Kirkland Lake (Kerr-Addison, Young-Davidson, Beattie), and Rouyn-Noranda (Francoeur 3) (Figure 2) were reviewed. These deposits are typically characterized by enrichments in Au, K_2O, Rb, and S (Dinel et al., 2008; Moritz and Crocket, 1991; Kishida and Kerrich, 1987; Martin, 2012; Bigot, 2012; Couture and Pilote, 1993) which is consistent with the Island Gold deposit (Table 4). Other common enrichments in these deposits east of the KSZ often include As, Ba, CO_2 (and/or volatiles/LOI), SiO_2, and W (Dinel et al., 2008; Moritz and Crocket, 1991; Kishida and Kerrich, 1987; Martin, 2012; Bigot, 2012; Couture and Pilote, 1993). These enrichments also commonly occurred due to auriferous vein-related alteration at the Island Gold deposit but did not consistently occur in each host lithology and all altered/less-altered pairs (Table 4). Sodium enrichment in the wall-rock around auriferous quartz veins is common in orogenic gold deposits east of the KSZ in the Wawa-Abitibi terrane (e.g. Dinel et al., 2008; Kishida and Kerrich, 1987; Martin, 2012; Couture and Pilote, 1993). However, sodium depletion occurs at the Island Gold deposit (Table 4) and some deposits east of the KSZ such as the Beattie Gold deposit (Bigot, 2012) as well.

Gold mineralization-related alteration minerals in the deposits discussed above that are located east of the KSZ in the Wawa-Abitibi terrane typically include carbonate minerals, chlorite, sericite and/or potassium feldspar, plagioclase, quartz, and sulphide minerals (Dinel et al., 2008; Moritz and Crocket, 1991; Kishida and Kerrich, 1987; Martin, 2012; Bigot, 2012; Couture and Pilote, 1993; Smith et al., 1987a). Biotite is not typically an alteration mineral at these deposits but is an alteration mineral in gabbro and Webb Lake stock-hosted ore zones at the Island Gold deposit. In addition, potassium feldspar was not a major alteration mineral in any lithologies at Island Gold. All of the other minerals discussed above are significant alteration minerals at the Island Gold deposit (Section 4.1).

These differences in the mineralogical and chemical signature of alteration at the Island Gold deposit relative to the auriferous alteration at these other orogenic gold deposits suggests that alteration envelopes around auriferous veins in these deposits can vary and no single model fits for all deposits. However, the overall similarity of the auriferous alteration at Island Gold relative to these deposits east of the KSZ may support the correlation of the GLDZ with fault

systems east of the KSZ (as proposed in Leclair et al., 1993) and, at least suggests a similar genetic process for these orogenic gold deposits.

5.6 Non-auriferous alteration

5.6.1 Carbonate-sericite alteration

The gold-barren, carbonate-sericite alteration zone that was observed in drill core approximately 500 m SSW of the main Island Gold Zones has a notable absence of sulphidization and silicification/quartz veining which allows it to be distinguished from alteration envelopes associated with auriferous V_{GD} or V_1-V_2 quartz veins. Similarly, the fluid responsible is probably different than the auriferous fluid responsible for mineralization at the Island Gold deposit and reasons for this are discussed below. Considering the significant intensity of this carbonate-sericite alteration (Figure 13, Figure 15), mass gains of Au (0.01 ppm) and S (0.01 ppm; Table 7) are negligible compared to the typical enrichments observed due to alteration associated with auriferous quartz veining (e.g. Table 5, Table 6). In addition, unlike the alteration associated with auriferous quartz veins, consistent sodium depletion was not observed (Table 4).

Based on the most consistent and significant enrichments relative to least-altered concentrations, this hydrothermal alteration was likely generated from a fluid especially enriched in C, CO_2, Ca, and K (Table 4; Table 7). This is reflected by the presence of carbonate minerals and sericite in the altered sample (Figure 15). Tourmaline was observed in greater proportions in the altered sample which explains the elevated boron content relative to the least-altered sample (Table 7). It is unclear whether tourmaline post-dates this alteration or is related to the carbonate-sericite alteration event and is simply a late alteration mineral phase. Tourmaline was confirmed to post-date the alteration associated with V_{GD}, V_1-V_2, and V_3 quartz veins through the examination of multiple alteration envelopes (Section 5.6.3). The tourmaline was occasionally present in these vein types and their associated alteration envelopes while in other occasions it was completely absent. In the case of this carbonate-sericite alteration zone, only one zone was encountered in drill core during site visits so it could not be confirmed that the tourmaline is unrelated to this carbonate-sericite alteration. Similarly, this alteration was not observed to coincide with any other lithologies or any auriferous zones. As a result, the source of this fluid and the timing of this uncommon alteration at the Island Gold deposit is unclear.

5.6.2 V_3 vein-related alteration

Alteration resulting from V_3 veining in the silica-poor diorite–monzodiorite and gabbro/lamprophyre was studied to confirm that it is distinctly different from the alteration related to auriferous quartz veins and, subsequently, provide further evidence that these lithologies post-date gold mineralization. Auriferous quartz veining (V_{GD} and V_1-V_2) at the Island Gold deposit results in the significant and consistent enrichment of Au, K_2O, Rb, S, and Te in all altered/least-altered pairs studied, regardless of their protolith (Table 4). The fluid that generated the V_3 veins was not derived from the same fluid that generated the V_{GD} and V_1-V_2 veins because Au, K_2O, Rb, S, and Te are not all consistently enriched in altered/least-altered pairs subject to alteration by V_3 veins (Table 4). For comparison, a sample of gabbro directly adjacent to V_1-V_2 auriferous veins exhibited significant mass gains of Au (5.7 ppm), K_2O (1.6 wt%), Rb (29 ppm), S (4.0 wt%), and Te (0.37 ppm) relative to a least-altered sample of gabbro (Table 8). Starting with the gabbro/lamprophyre, consistent mass gains in Au, K_2O, and Rb were observed but consistent gains of S and Te were not observed due to alteration related to V_3 veining (Table 4). In addition, despite the altered sample being directly adjacent to a V_3 vein, gains of Au (0.05 ppm), K_2O (0.32 wt%), and Rb (8.23 ppm) were relatively minor. Similarly, in the silica-poor diorite–monzodiorite, consistent mass gains in Au, S, and Te were observed but despite the altered sample being directly adjacent to a V_3 vein, the concentration gains were relatively insignificant (0.07 ppm, 0.15 wt%, and 0.10 ppm, respectively). These are minor compared to the typical gains related to auriferous quartz veining (e.g. Table 8). Furthermore, K_2O and Rb were both consistently depleted as a result of this alteration (Table 4). As a result, V_3 veins could not have been generated from the same fluid as V_{GD} or V_1-V_2 veins.

Based on macroscopic observation, the small alteration envelopes associated with V_3 veins often have notable variations in intensity and mineralogy even within the same lithology. In many cases, there were no macroscopically visible alteration envelopes associated with these veins (Figure 7C) while in other cases, the alteration envelope, although relatively small compared to those associated with V_{GD} and V_1-V_2 veining, was clearly visible. Particularly when V_3 veins are hosted in an intrusion of gabbro/lamprophyre or silica-poor diorite–monzodiorite, and this intrusion is overprinting part of an alteration envelope associated with auriferous quartz veining, the V_3 vein-related alteration appears more intense (Figure 30, Figure 34A, B). However, these more intense alteration envelopes may be related to the tourmalinization event as

tourmaline is also present in these veins (Figure 30, Figure 34A, B; Section 5.6.3). Regardless, the alteration associated with V_3 veins is different from the V_{GD} and V_1-V_2 veins which both have consistent mineralogical and textural alteration envelopes irrespective of their spatial location, as long as they are located within the same lithology. The inconsistency of the V_3 vein-related alteration suggests the composition of the vein-filling fluid in V_3 veins varies from one vein to the next and is dependent on the host rock, which is not always the same. This is thought to explain the varying intensity of alteration and why the chemical gains and losses determined from study of silica-poor dioritic–monzodioritic altered/least-altered pairs are different from those determined via study of altered/least-altered pairs of gabbro/lamprophyre (Table 4). V_3 veins are interpreted as extensional veins (Jellicoe, 2019) and are typically relatively small and discontinuous. As a result, unlike the large, continuous, extensional V_{GD} veins and shear-related V_1-V_2 vein systems and associated structures that are the conduits that provided the auriferous external fluid to the deposit (Jellicoe, 2019), the fluids within V_3 veins are more likely to have been locally sourced. This suggests that local dissolution-precipitation may have been the vein-filling process which does not require an external fluid source (e.g. Kenis, 2004). In summary, V_3 veins resulted in minor alteration and local remobilization of certain elements which vary depending on the host rock in which the veins formed.

Alteration related to V_3 veins was studied primarily in the silica-poor diorite–monzodiorite and gabbro/lamprophyre which post-date V_{GD} and V_1-V_2 veining. This is because the intensity of the alteration related to V_{GD} and V_1-V_2 veining is more intense than the alteration related to V_3 veins. This makes V_3 vein-related alteration often indistinguishable in pre-gold mineralization lithologies because they are often at least weakly-altered by V_1-V_2 veins within mine workings. In addition, in any given pre-gold mineralization lithology, it is not known if alteration is directly-related to a V_3 vein or is partly related to variations in V_{GD}/V_1-V_2 vein-related alteration. Non-auriferous, V_3 vein-related alteration was not the main focus of this thesis and was only studied in a limited number of samples.

5.6.3 Tourmalinization / V_4 veins

Tourmaline is sporadically present in all lithologies, with the exception of diabase–quartz diabase intrusions, and manifests as disseminated tourmaline crystals or clusters of tourmaline that concentrates in ribbons along existing structures (e.g. Figure 25B). These ribbons of

tourmaline are referred to as V_4 veins (Jellicoe, 2019) and occasionally have minor quartz and carbonate minerals associated with them (e.g. Figure 25B). Based on this information, a boron-rich hydrothermal fluid that preferentially propagated along pre-existing structures is interpreted to be responsible for tourmalinization and V_4 veins. Tourmaline overprints primary and metamorphic minerals as well as V_{GD}, V_1-V_2, and V_3 vein-related alteration minerals indicating that it post-dates these veins (Section 4.1). Tourmalinization is likely unrelated to the main gold mineralization events because least-altered rocks which contain tourmaline still have gold grades that are equivalent to other least-altered samples without any tourmaline. In many cases, tourmaline ribbons/veins have no visible alteration envelope. However, if they coincide with existing veins, they occasionally result in intensification of the surrounding alteration envelopes (e.g. Figure 30, Figure 34A). This suggests that the boron-bearing fluid may have resulted in the local remobilization of some elements. Sampling of tourmaline-related alteration envelopes that are sufficiently isolated from and unaffected by other alteration events was not conducted in this thesis. Further investigation of the tourmalinization event is recommended in Section 7.0.

5.7 Source(s) of sulphur and gold-bearing fluids

Potential sources of the sulphur and gold introduced to the Island Gold deposit by the auriferous fluids include: the mantle, meteoric water, igneous rocks, and/or sedimentary rocks (e.g. Phillips and Groves, 1983; Hronsky et al., 2012; Xue et al., 2013; Tomkins, 2013; Agangi et al., 2016). Mass-independent fractionation (MIF) of sulphur is only known to occur on Earth due to surficial processes in the Archean (Farquhar et al., 2001) and subsequently can be used to determine whether sulphur in Archean ore deposits was sourced from meteoric water or sedimentary rocks with incorporated sulphur that was once present in the Archean atmosphere.

Determining the source(s) of sulphur can also be used to identify potential source(s) of gold. Sulphide minerals are intimately associated with the auriferous quartz veins (Section 4.1) and there are inclusions of gold within the pyrite grains (refractory gold) at the Island Gold deposit (Figure 9C). This suggests gold and sulphur were introduced to the deposit by the same fluid. Furthermore, sulphide complexes commonly transport gold in hydrothermal fluids (Loucks and Mavrogenes, 1999). Although this demonstrates that gold and sulphur were likely carried by the same fluid, it is possible that they have different sources. For example, the fluid could have been derived from the mantle, the cooling of an igneous body or dehydration reactions due to

metamorphism while gold may have been scavenged later from certain lithologies as this fluid percolated through them or propagated along structural conduits. Alternatively, the gold could have been derived from any of these potential fluid sources along with the fluid itself (Phillips and Groves, 1983; Hronsky et al., 2012; Xue et al., 2013; Tomkins, 2013; Agangi et al., 2016).

The non-zero $\Delta^{33}S$ and $\Delta^{36}S$ values of sulphides from iron formations (Section 4.5) within the study area are consistent with MIF sulphur. MIF sulphur has been documented in a wide variety of Archean sedimentary rocks (e.g. Farquhar et al., 2000; Hou et al., 2007). The negative $\Delta^{33}S$ values in sulphides from iron formations at the Island Gold deposit indicate that the sulphur was sourced from a negative $\Delta^{33}S$ reservoir. These iron formations would have been enriched in the oxidized species (SO_4^{2-}) produced by photochemical oxidation of volcanic sulphur species in the Archean atmosphere (Farquhar et al., 2001). The range of $\delta^{34}S$ values in sulphides from iron formations (-1.33‰ to 19.60‰; Figure 60) suggests sulphur isotope fractionation that is characteristic of a relatively low sulphate reservoir which is typical in the Archean (Canfield and Raiswell, 1999). This variation in $\delta^{34}S$ values is suggestive of a later reduction process that caused this fractionation. Previous studies have interpreted this fractionation to be due to biological processes such as microbial sulphate reduction (e.g. Goodwin et al., 1976; Lambert and Donelly, 1992). Microbial reduction would result in MDF (Farquhar et al., 2000) and, as a result, this secondary process would not result in a significant change in the $\Delta^{33}S$ value.

The $\Delta^{33}S$ and $\Delta^{36}S$ values of sulphides from V_1 and V_2 vein types and their associated alteration envelopes are all very close to zero and these values are considered to reflect dominantly mass-dependent fractionation (e.g. Farquhar et al., 2000; Xue et al., 2013). One $\Delta^{36}S$ value from an altered gabbroic sample has an anomalous $\Delta^{36}S$ value indicative of MIF sulphur (Section 4.5). However, unlike $\Delta^{33}S$, there is more uncertainty associated with $\Delta^{36}S$ values based on historical analyses of the standard IAEA-S1 at this lab (±0.008‰ for $\Delta^{33}S$ versus ±0.30‰ for $\Delta^{36}S$; Wu, personal communication, 2018). As a result, $\Delta^{33}S$ is given priority over $\Delta^{36}S$ when differentiating between MIF and MDF sulphur. The consistent slightly negative $\Delta^{33}S$ value may also suggest a small contribution from a source with negative $\Delta^{33}S$. A second alternative involves the mixing of two sulphur sources: one with positive $\Delta^{33}S$ and one with negative $\Delta^{33}S$. However, the small range of $\Delta^{33}S$ values for these samples, as well as the probability of the mixing of two sources producing values equivalent to MDF ($\Delta^{33}S \approx 0$), makes this interpretation unlikely.

Continuing with the first interpretation, the minimal MIF sulphur indicates that meteoric water and the metamorphism of sedimentary rocks were not the dominant sources of sulphur. Instead, sulphur of mantle parentage is more probable. The negative $\Delta^{33}S$ sulphur could have been incorporated due to limited leaching of sulphide-rich iron formations (which have negative $\Delta^{33}S$ values; Figure 60) as the fluid moved up and along the GLDZ. Sulphide-rich iron formations separate the first and second cycles of volcanism and the second and third cycles of volcanism in the Michipicoten greenstone belt (Sage, 1994). These iron formations are volumetrically minor compared to other lithologies within the Michipicoten greenstone belt (Sage, 1994). However, the high sulphide content in the iron formations studied in this thesis (e.g. Figure 22A) suggests they are likely a significant reservoir of sulphur in this greenstone belt because other observed lithologies typically contain relatively low amounts of sulphur.

In summary, most of the sulphur associated with the main gold-mineralization event at the Island Gold deposit is most likely originally of mantle/igneous parentage, sourced from: (1) a sulphur-rich mantle fluid, (2) an exsolved sulphur-bearing fluid from a crystallizing intrusive body, and/or (3) the leaching of sulphur from igneous rocks during fluid propagation. The gold may be derived from the same source of the sulphur or leached during the movement of the sulphur-bearing fluid through the crust.

The $\Delta^{33}S$ value obtained from pyrite in a V_{GD} vein is well outside the range of $\Delta^{33}S$ values found in sulphides associated with V_1 and V_2 auriferous quartz veins (Figure 60), even if analytical uncertainty is considered. This indicates that the sulphur in V_{GD} veins has a different source than the sulphur present in the V_1 and V_2 veins. The V_{GD} veins are interpreted to have formed prior to the formation of the V_1 and V_2 veins (Jellicoe, 2019). These findings suggest that V_{GD} veins formed from a unique fluid source which supports that the V_{GD} veins formed separately from V_1-V_2 veins. The $\Delta^{36}S$ value of negative 0.05‰ is consistent with MDF sulphur. However, as discussed earlier in this section, there is notable uncertainty associated with $\Delta^{36}S$ values relative to $\Delta^{33}S$ values. The positive $\Delta^{33}S$ value of 0.143‰ obtained from pyrite in a V_{GD} vein falls close to the upper limit of the MDF field. In the absence of MIF and processes related to metabolic activity, only small deviations of $\Delta^{33}S$ from 0‰ of ± 0.05‰ are possible (Farquhar et al., 2007a). Larger deviations from zero can result from either metabolic processes or MIF. Firstly, metabolic mixing of MDF sulphur reservoirs with large differences in $\delta^{34}S$ (Farquhar et al., 2007a) can cause $\Delta^{33}S$ deviations from 0‰ of ± 0.2‰ (Farquhar and Wing, 2003). As a

result, it is possible that MDF sulphur may have been affected by processes related to surficial microbial metabolism producing this intermediate $\Delta^{33}S$ value. However, this is unlikely because all of the sulphides that fall within the MDF field (Figure 60) have a very narrow range of $\delta^{34}S$ values (1.2–1.9‰) and therefore only a maximum difference of 1.7‰. Mixing of components with a difference of this magnitude will not produce a $\Delta^{33}S$ value as large as 0.143 (Farquhar et al., 2007a). Furthermore, non-zero $\Delta^{33}S$ values produced due to this metabolic mixing process are not common (Farquhar and Wing, 2003). Alternatively, this $\Delta^{33}S$ value could have been produced from the mixing of a typical MDF sulphur source ($\Delta^{33}S \approx 0$) and a positive $\Delta^{33}S$ MIF sulphur source. Regardless of whether this non-zero $\Delta^{33}S$ value was produced by MDF sulphur affected by near-surface metabolic activity or MIF, the sulphur must have been present at or near surface prior to the gold mineralization event. This contribution from surficial sulphur suggests that leaching of sulphur from sedimentary units as the auriferous fluid propagated through structural conduits was taking place. Alternatively, metamorphism of a combination of igneous and sedimentary rocks could produce a sulphur-rich fluid with this isotopic signature. Juvenile MDF sulphur ($\Delta^{33}S \approx 0$) could have been present in the fluid originally or leached from igneous rocks of mantle parentage during fluid propagation. These interpretations should be used with caution because only one sample from the V_{GD} vein type was analyzed. Although analytical uncertainties associated with $\delta^{34}S$ and $\Delta^{33}S$ are small (Section 3.8.2), additional sulphur isotopic analyses of sulphides from these veins are recommended to confirm these findings.

The silica-poor diorite–monzodiorite typically hosts minor disseminated pyrite regardless of its proximity to ore zones (e.g. Figure 33A, B). The sulphur in this pyrite has a unique isotopic signature (Figure 60) which suggests that it is from a different source than sulphur from the ore zones. This also supports the interpretation that this lithology post-dates gold-mineralization because, despite being commonly found adjacent and parallel to auriferous veins, the sulphides in the veins have different $\Delta^{33}S$ and $\Delta^{36}S$ values when compared to the silica-poor diorite–monzodiorite (Section 4.5). The positive $\Delta^{33}S$ value of pyrite from the silica-poor diorite–monzodiorite suggests MIF took place but this sulphur was sourced from a reduced MIF sulphur reservoir (Farquhar et al., 2000). This sulphur was originally derived from an Archean sedimentary source but is not derived from the same reservoir as the oxidized sulphur in the banded iron formations which exhibits negative $\Delta^{33}S$ values. A possible source of this sulphur is melting and assimilation of a sulphide-rich sedimentary rock with positive $\Delta^{33}S$ values during

pluton transport and emplacement. Partially melted xenoliths have been observed in this lithology (Figure 32) which supports that this intrusive did melt and assimilate earlier lithologies. However, there are no known sedimentary rocks in the region with appropriate positive $\Delta^{33}S$ values. This may be because extensive multiple sulphur isotopic studies of lithologies in the Michipicoten greenstone belt have not been conducted.

Previous multiple sulphur isotopic studies of Archean gold deposits in the Yilgarn Craton, Superior Province, and Kaapvaal Craton and have yielded contrasting results and interpretations. Some studies have found that MDF sulphur dominates which suggests a mantle/igneous source of sulphur and, by association, gold (e.g. Xue et al., 2013). Other studies have found that most of the deposits examined display varying contributions from MIF sulphur. This is interpreted to be a result of the metamorphism of a combination of sedimentary and igneous rocks (e.g. Agangi et al., 2016; Selvaraja et al., 2017). Results from this study of the Island Gold deposit largely support a mantle/igneous source of sulphur for sulphides associated with V_1 and V_2 veins. However, sulphides from V_{GD} veins are composed of MDF sulphur affected by surficial metabolic activity or a combination of surficial MIF sulphur in addition to juvenile MDF sulphur. This is likely due to metamorphism and/or leaching of sulphur from a combination of sedimentary rocks and mantle-derived igneous rocks.

5.8 Relative and absolute ages

The voluminous dacitic rocks are crosscut or stratigraphically overlain by all lithologies and, as a result, they are the oldest lithology at the Island Gold deposit. Previous U-Pb zircon geochronological studies of the felsic–intermediate volcanic rocks of the Wawa Assemblage yielded ages ranging from 2749 ± 2 to 2728 ± 2.7 Ma (Turek at al., 1982, 1992). The age of 2735 ± 8 Ma obtained in this study from a least-altered dacitic sample (Section 4.6) falls within this range. Similarly, the age of 2738 ± 9 Ma obtained from an altered dacitic sample in an ore zone is also consistent with these previous studies (excluding spot locations situated on the anomalous uniform CL crystals and rims described in Section 4.6 and discussed later in this section). These two ages from this study are identical within error. As a result, the zircons in these samples are believed to have crystallized at approximately the same time.

Banded iron formation layers are occasionally interlayered with the dacitic rocks. The larger Michipicoten iron formation caps the cycle 2 felsic–intermediate volcanic rocks (Sage,

1994), separating them from the mafic volcanic rocks to the north of the Island Gold deposit. A U-Pb age of 2728.8 ± 2.7 Ma was obtained from the felsic–intermediate volcanic rocks of the Wawa Assemblage, directly below the Morrison No. 1 iron range (Turek et al., 1988, 1992). This iron range is interpreted to be part of the Michipicoten iron formation (Sage, 1994) and is located north of the Island Gold deposit. A U-Pb date obtained from the felsic–intermediate volcanic portion of the overlying Catfish Assemblage is 2717 ± 11 Ma (Smith et al., 1987b). As a result, the Michipicoten iron formation was deposited between *c.* 2729 and *c.* 2717 Ma. In summary, some iron formation layers are of similar age to the dacitic rocks, however, the majority are younger.

The gabbro at the Island Gold deposit crosscuts the dacite (Section 4.1.4.1) and therefore, is younger. This lithology may have been emplaced during multiple intrusion events but samples taken throughout the deposit are mineralogically and chemically equivalent. Although the gabbro was not directly observed cross-cutting the iron formation, minor iron formations are occasionally found interbedded within the dacite and as a result, it is likely that this gabbroic intrusion, at the least, post-dates these minor iron formations. The relative timing between the larger Michipicoten iron formation that stratigraphically overlies the second cycle dacite (Sage, 1994) and the gabbro is not known because cross-cutting relationships were not observed.

The Webb Lake stock intrudes the dacite, iron formations, and gabbro (Section 4.1.5.1) and therefore, post-dates these lithologies. The Webb Lake stock was dated at 2724 ± 4.3 (Jellicoe, 2019). This age, and the age of the dacite, effectively bracket the age of the Michipicoten iron formation.

The dacite, gabbro, and the Webb Lake stock were observed to host V_{GD} and V_1-V_2 veins if they were located in an auriferous zone (Section 4.1). Iron formation was not observed near occurrences of V_{GD} or V_1-V_2 veins, but because the Webb Lake stock post-dates the iron formation and hosts these auriferous veins, it is likely that iron formation pre-dates these veins as well. Shearing associated with the emplacement of V_1-V_2 veins is observed deforming the V_{GD} veins (Figure 7A). As a result, the V_{GD} veins are older than the V_1-V_2 veins (Jellicoe, 2019). V_1 and V_2 veins are believed to have formed synchronously (Jellicoe, 2019) based on contradicting and often ambiguous cross-cutting relationships (Section 4.1.1.1).

The gabbro/lamprophyre is observed cross-cutting the dacite and gabbro. It is not cross-cut or altered by V_1-V_2 veins despite being commonly found within these auriferous quartz vein

corridors (Section 4.1.6.1). It also does not contain economic gold grades despite being directly adjacent to these veins (Section 5.6.2). Therefore, this lithology intruded after the auriferous quartz veining events and is younger than the lithologies discussed above in this section.

The quartz diorite was directly observed as xenoliths within the silica-poor diorite–monzodiorite (Figure 32A) and as a result, the quartz diorite is younger than the diorite–monzodiorite. The quartz diorite is also present as a separate intrusive body on the 600 level but was not directly observed because it was inaccessible during site visits. A cross-cutting relationship between this minor lithology and the gabbro/lamprophyre was not observed. However, based on the fresh appearance of the quartz diorite in thin section and lack of significant deformation (Figure 32B, D), it qualitatively appears that this lithology has been subject to less metamorphism and deformation and as a result, is possibly younger than the gabbro/lamprophyre (Figure 29A). The quartz diorite was not observed adjacent to auriferous quartz veins so a timing relationship could not be determined. However, if this lithology is younger than the gabbro/lamprophyre, it must also post-date the V_{GD} and V_1-V_2 veins.

Similar to the gabbro/lamprophyre, the silica-poor diorite–monzodiorite cross-cuts V_1-V_2 auriferous veins and is not altered by them (Figure 34C). It also does not have notable gold enrichment when directly adjacent to these veins. As a result, the silica-poor diorite–monzodiorite intruded after the formation of the V_1-V_2 auriferous veins. The silica-poor diorite–monzodiorite appears to ambiguously cross-cuts the gabbro/lamprophyre in a few cases. However, both of these intrusions are relatively minor and commonly parallel each other within mine workings so clear, high-angle, cross-cutting relationships are rare. The silica-poor diorite monzodiorite and the quartz diorite xenoliths within appear to have been subject to less metamorphism (have a larger proportion of primary minerals) and appear less deformed than the gabbro/lamprophyre (Figure 33A, B; Figure 32; Figure 29A). This tentatively suggests that the silica-poor diorite–monzodiorite is younger than the gabbro/lamprophyre but this warrants further investigation (Section 7.0). Besides the gabbro/lamprophyre, the silica-poor diorite-monzodiorite is younger than the quartz diorite and all of the lithologies and veins types discussed above in this section. The silica-poor diorite–monzodiorite has been dated at 2672.2 ± 3.5 Ma (Jellicoe, 2019).

V_3 quartz veins post-date all of the lithologies and veins discussed above in this section, because these non-auriferous extensional veins were observed in all lithologies and cross-cut

V_{GD} and V_1-V_2 veins (Section 4.1.1.1). It is interpreted that the tourmaline post-dates the structures and the lithologies it occurs in. Tourmalinization, including the formation of the tourmaline ribbons (V_4 veins) is believed to post-date V_3 veining as these ribbons invade V_3 veins (Jellicoe, 2019; e.g. Figure 30). Tourmaline is probably not present in the diabase–quartz diabase because this unit post-dates the tourmalinization event. Alternatively, the diabase–quartz diabase is relatively undeformed and simply does not contain structures for a B-rich fluid to propagate along and precipitate tourmaline. If the second alterative is true, tourmalinization may have occurred after the of intrusion the diabase–quartz diabase.

Diabase–quartz diabase dykes have only been subject to minor greenschist-grade metamorphism and sharply cut all other lithologies and quartz vein types. Therefore, this lithology is the youngest. The age of these dykes is uncertain as both late Archean and Proterozoic diabase dykes are located in the area (Sage, 1994). These are interpreted to be part of the Matachewan dyke swarm (Jellicoe, 2019; Section 5.1.8) which has been dated at 2473 +16/-9Ma (Heaman, 1997). The stratigraphy, relative timing relationships, absolute timing, and associated interpretations regarding the lithologies discussed above are summarized in Table 19 (Appendix B).

The spot locations situated on the uniform CL zircons/rims in the altered dacitic sample that yielded anomalous Proterozoic ages ranging from *c.* 975 to 1499 Ma (Section 4.6) are believed to have formed due to one or multiple alteration event(s). It was originally suspected that these anomalous zircons/rims formed as a result of the intense alteration related to the emplacement of the V_1-V_2 auriferous quartz veins. However, the cause of this zircon growth/alteration is not related to gold mineralization because the silica-poor diorite–monzodiorite intrusive lithology, that cross-cuts the V_1-V_2 gold-bearing veins and post-dates gold mineralization, yielded a U-Pb age of 2672.2 ± 3.5 (Jellicoe, 2019). The smaller, anhedral, and often fractured zircons in the altered sample (e.g. Figure 61B–D) suggest that zircon dissolution rather than growth/alteration resulted from the emplacement of the V_1-V_2 veins.

These anomalous CL zircons may be a result of the intrusion of the diabase–quartz diabase dykes in the area that have Proterozoic ages (Leech et al., 1963; Sage, 1994). However, these dykes typically do not cause significant visible alteration of the surrounding wall-rock and as a result, it is likely that the alteration associated with the uniform CL zircons was not caused by these dykes. In addition, the diabase–quartz diabase intrusions were not observed directly

proximal to either sample location. However, diabase–quartz diabase dykes were observed within the drift from which the altered sample was taken. The diabase–quartz diabase dykes observed within mine workings are believed to be part of the Matachewan dyke swarm (Jellicoe, 2019) which are Paleoproterozoic (Heaman, 1997). If this interpretation is correct, zircon growth/alteration resulting from these dykes would not have produced Meso–Neoproterozoic aged zircon. However, younger Proterozoic diabase dykes have been observed in the Michipicoten greenstone belt as well (Leech et al., 1963; Sage, 1994) so it is possible that these dykes are younger than believed.

Alternatively, these Proterozoic-age zircons could be a result of the emplacement of the V_3 extensional veins, or later tourmalinization, both of which tend to concentrate within the shear zones that host the V_1-V_2 veins. Both V_3 veins and tourmaline were observed within the ore zone from which the altered sample was taken. However, these events are believed to pre-date the intrusion of the diabase–quartz diabase dykes because neither tourmaline nor V_3 veins were observed within the diabase–quartz diabase. Alternatively, these zircons could be related to the alteration event that resulted in the sporadic growth of chloritoid in certain areas and lithologies (Section 5.2). These Proterozoic-age zircons could also be a result of an unrecognized fluid pulse along, or reactivation of, the shear zone that hosts these auriferous quartz veins. At the Young-Davidson deposit, monazite U-Pb ages are consistent with a Paleoproterozic alteration event at 1730 ± 5 Ma (Zhang et al., 2014) and were attributed to late hydrothermal reactivation. Although these are two temporally unrelated events, a similar process may have taken place at the Island Gold deposit resulting in the generation of these anomalous Meso–Neoproterozoic ages. However, the specific timing of the Proterozoic alteration event(s) recorded by zircon at the Island Gold site cannot be resolved with the current data set.

6.0 Summary and conclusions

The five main objectives of this thesis focusing on the Island Gold deposit were:

1) Determine the protoliths of major lithologies and effects of metamorphism;
2) Characterize the alteration envelopes associated with various gold-bearing quartz veins and compare to the alteration at other orogenic gold deposits east of the Kapuskasing Structural Zone;
3) Establish mineralogical indicators and geochemical vectors for gold mineralization;
4) Constrain the source of the gold-bearing fluid using sulphur isotopes; and
5) Determine the age(s) of gold mineralization.

The conclusions pertaining to each of these objectives are summarized in order below.

6.1 Protoliths and metamorphism

The interpreted protoliths of lithologies observed at the Island Gold deposit are listed below in order from oldest to youngest. Mine terms used to refer to these units are included in parentheses when applicable.

1) Dacitic volcanic rocks: Tuffs, hypabbysal intrusives, flows, and pyroclastic breccias (T2, I2, V2)
2) Banded-massive iron formation (IF)
3) Gabbro (I3G)
4) Tonalite–trondhjemite (Webb Lake stock: I1JM)
5) Lamprophyre (Spessartite) or gabbro (Sub-volcanic equivalent to ocean island basalt or continental flood basalt) (I2H)
6) Quartz diorite
7) Silica-poor diorite–monzodiorite (I2M)
8) Diabase–quartz diabase (I3DD)

Protoliths 1 to 4 (above) are pre-gold mineralization lithologies. A stratigraphic chart that summarizes the timing, textures, and mineralogy for each lithology is included in Appendix B (Table 19). The interpreted primary minerals in each lithology prior to metamorphism and alteration is also included. All lithologies at the Island Gold deposit were affected by some degree of greenschist-grade metamorphism. Least-altered samples of all lithologies often contain

metamorphic minerals (e.g. actinolite, carbonates, chlorite, chloritoid, epidote, hematite, ilmenite, magnetite, quartz, sodic plagioclase, titanite, and white mica) which commonly replace primary minerals. Metamorphism appears to have had a weaker effect on the quartz diorite and the silica-poor diorite–monzodiorite compared to most other lithologies at this deposit, tentatively suggesting that these two lithologies were emplaced after peak metamorphism. The diabase–quartz diabase intrusions have been affected the least by metamorphism and this indicates that they post-date the main greenschist-grade metamorphic event which occurred during D2 deformation (Jellicoe, 2019).

6.2 Vein-related alteration

Alteration related to V_1-V_2 veining at the Island Gold deposit results in the significant and consistent enrichment of Au, K_2O, Rb, S, and Te and typically Na_2O depletion in alteration envelopes hosted by dacite, gabbro, and the Webb Lake stock. The consistent enrichment and depletion of these elements supports that V_1-V_2 veins hosted by these lithologies precipitated from the same gold-rich fluid. Additional chemical enrichments and depletions specific to each lithology are summarized in Table 4. Alteration minerals associated with V_1-V_2 auriferous quartz veining mainly consist of biotite, Ca-Mg-Fe carbonates, chlorite, plagioclase, quartz, sulphides (pyrite ± pyrrhotite ± chalcopyrite), and white mica (muscovite ± phengite). The alteration mineral assemblage varies depending on the lithology being altered (Table 19; Appendix B). The minerals in alteration envelopes associated with V_1-V_2 veining remain consistent with varying distance parallel to the GLDZ and elevation. Silicification of the alteration envelope may increase with depth.

The chemical and mineralogical signature of alteration related to V_{GD} veins in the dacite is similar to the alteration related to V_1-V_2 veins in the same lithology. It is therefore extrapolated that gabbro or Webb Lake stock-hosted alteration envelopes associated with V_{GD} veins would have similar mineralogical and chemical signatures as those associated with V_1-V_2 veins.

V_3 non-auriferous veins resulted in minor alteration and inconsistent local remobilization of various elements (Table 4) that are dependent on the host lithology in which they form. When present, small alteration envelopes associated with these veins often have notable variations in intensity and mineralogy even within the same lithology. The fluids that generated V_3 veins were

likely locally sourced and the fluid composition is a direct product of the surrounding wall rock composition. Conversely, V_1-V_2 and V_{GD} veins were generated from exotic, gold-enriched fluids that propagated along structural conduits, resulting in consistent and predictable alteration zones.

Alteration envelopes associated with auriferous quartz veins (V_1-V_2 and V_{GD}) are relatively symmetrical and range from a few centimetres to 10 m or more perpendicularly outwards from a central vein. Alteration envelopes associated with V_{GD} veins are generally smaller than those associated with V_1-V_2 veins of comparable size. Similarly, alteration envelopes hosted by the Webb Lake stock are smaller than those hosted by the dacite or gabbro. V_3 veins have no visible alteration envelope or small alteration envelopes that are typically less than 0.2 m perpendicularly outwards from the vein/wall rock contact.

Orogenic gold deposits east of the Kapuskasing Structural Zone (KSZ) such as Hoyle Pond, Dome, Kerr-Addison, Young-Davidson, and Francoeur 3 generally have similar alteration mineral assemblages and chemical enrichments associated with auriferous quartz vein-related alteration. One notable difference is sodium enrichment is more common at these deposits but sodium depletion consistently occurs at the Island Gold deposit. Furthermore, potassium feldspar was not a significant alteration mineral in any lithologies at the Island Gold deposit but is often an alteration mineral at these other deposits. These notable differences in the mineralogical and chemical signature of alteration suggests that alteration envelopes around auriferous veins in orogenic gold deposits can vary and no single model fits for all deposits. Aside from these differences, the alteration mineral assemblages and chemical signatures of the alteration observed in these gold deposits east of the KSZ are similar to those identified at the Island Gold deposit. This overall consistency of the alteration between these deposits and the Island Gold deposit may support the correlation of the Goudreau Lake Deformation Zone with major fault systems east of the KSZ (as proposed in Leclair et al., 1993) and, at least suggests a similar genetic process for these orogenic gold deposits.

6.3 Mineral indicators and geochemical vectors for gold mineralization

The most reliable geochemical vectors towards mineralized zones include Au, K_2O, Rb, S, and Te enrichment. Other geochemical vectors include As, Se, and W enrichment and Na_2O depletion. Smoky quartz veins, veinlets, and flooding are the most reliable indicators for economic gold grades at the Island Gold deposit. In low-grade samples (< 4 g/t), pyrite correlates

well with gold grade. Proportions of alteration minerals such as biotite, carbonates, chlorite, quartz, sericite, and sulphides can be used as an approximate guide to help discern which zone of an alteration envelope a sample is from. This can be used to help provide a general estimate of gold grade (Section 4.1; Section 4.4; Figure 20; Figure 59). However, proportions of these minerals alone do not correspond reliably enough with gold content to differentiate between units with different cut-off grades. Increased proportions of chlorite and carbonate minerals relative to unaltered rock can be used to identify the weakly-altered outer margins of alteration envelopes associated with auriferous quartz veins.

6.4 Source(s) sulphur and the gold-bearing fluid

Despite the availability of sources of MIF sulphur in nearby iron formations, the majority of the sulphur in, and associated with, the auriferous V_1 and V_2 veins exhibits MDF. This indicates that most of the sulphur has a mantle or igneous parentage and did not come into contact with Archean atmosphere. The auriferous fluid that produced these veins was likely derived from the mantle, exsolved from a cooling intrusive body, or the dehydration of igneous rocks due to metamorphism. The gold was likely originally enriched in this fluid or sourced from the leaching of igneous rocks during fluid movement. A small amount of MIF sulphur may have been incorporated due to leaching of sedimentary units during fluid propagation.

Despite their alteration envelopes having similar chemical and mineralogical signatures, the V_{GD} veins formed earlier than the V_1-V_2 veins as a result of a separate gold mineralization event due to a unique gold-bearing fluid with a different sulphur source. The sulphur was likely derived from either MDF sulphur subject to near-surface metabolic processes or a combination of juvenile MDF and positive $\Delta^{33}S$ MIF sulphur sources. The MIF and surficial MDF sulphur would have been leached from sedimentary units as the auriferous fluid propagated through structural conduits or originally enriched in the fluid (assuming the fluid was of metamorphic origin). The juvenile MDF sulphur could have been present in the fluid originally or leached from igneous rocks during fluid propagation.

The unique isotopic signature of pyrite in the silica-poor diorite–monzodiorite supports the interpretation that this lithology post-dates gold mineralization and that these sulphide minerals did not form due to remobilization of existing sulphides from ore zones. Similar to

sulphur in the V_{GD} veins, the sulphur in this lithology suggests the presence of a positive $\Delta^{33}S$ MIF sedimentary sulphur source that is located down-dip or parallel to the GLDZ.

6.5 Timing of gold mineralization

Gold mineralization at the Island Gold deposit is younger than the Archean U-Pb LA-ICP-MS ages of 2738 ± 9 Ma and 2735 ± 8 Ma obtained from zircons in altered and least-altered dacitic samples. These ages are consistent with previous geochronological studies of the dacite. The spot locations yielding Proterozoic ages ranging from *c.* 975 to 1499 Ma, located on the anomalous, uniform CL zircons/rims in the altered sample, are believed to have formed due to alteration unrelated to auriferous quartz veining. The cause(s) of the alteration event(s) that resulted in the generation of these Proterozoic U-Pb ages are uncertain.

7.0 Suggested future work

Additional microprobe study of the minerals in least-altered samples of iron formation, gabbro/lamprophyre, quartz diorite, silica-poor diorite–monzodiorite, and diabase–quartz diabase is recommended. This will help classify observed minerals in these lithologies that are challenging to accurately classify using petrography and SEM-EDS techniques alone (e.g. carbonate minerals). This may further refine the interpreted protoliths of these lithologies and subsequently, their genetic history.

Alteration envelopes hosted by the gabbro and Webb Lake stock that are associated with V_{GD} veins should be studied petrographically and geochemically. This will confirm the interpretation in this thesis that alteration envelopes associated with V_{GD} veins and hosted by the gabbro and Webb Lake stock are chemically and mineralogically similar to alteration envelopes associated with V_1-V_2 veins. This was proven to be the case for dacite-hosted alteration envelopes.

As employed in this thesis for the study of a dacite-hosted alteration envelope, SEM-MLA techniques are recommended instead of point-counting for any further mineral modal proportion analyses. This method is believed to be more accurate and precise than point-counting, particularly for determining the modal proportions of accessory minerals. It is suggested that SEM-MLA analyses are also performed on a gabbro-hosted and a Webb Lake stock-hosted alteration envelope associated with V_1-V_2 veining to more accurately determine the modal proportions of minerals determined via point-counting techniques in this study.

Analysis of tourmalinization/V_4 veins and related alteration to determine the source of the boron-rich fluid and determine if it remobilizes existing gold is another potential avenue to study. Conducting work to better constrain the timing of the tourmalinization event is also suggested. Similarly, the non-auriferous sericite-carbonate alteration zone that was encountered warrants additional study in order to determine the relative timing and source of the fluid that generated this alteration zone. The mineralogical and chemical signature of this carbonate-sericite alteration and whether or not it is related to the tourmalinization event should be confirmed via examination of multiple carbonate-sericite alteration zones. Likewise, further study of chloritoid and its spatial distribution is also recommended to determine whether or not the chloritoid formed during late metamorphism or if it is a product of an alteration event unrelated to metamorphism.

Identify and photograph an unambiguous cross-cutting relationship between the silica-poor diorite-monzodiorite and the gabbro/lamprophyre. This will definitively determine the timing relationship between these two lithologies. Similarly, better constraining the timing of the quartz diorite relative to other lithologies at the Island Gold deposit by studying additional occurrences of the quartz diorite within mine workings is recommended. Absolute dating of the quartz diorite and gabbro/lamprophyre is also suggested.

It was originally suspected that the anomalous indistinct zircons and zircon rims in the altered sample were a result of the intense alteration related to the emplacement of V_1-V_2 veins. This study has shown that this is due to a Proterozoic post-gold mineralization event and, as a result, the age of gold mineralization could not be directly determined. It is possible that the alteration rims due to V_1-V_2 veining (if any) are too thin to be analyzed through traditional LA-ICP-MS of polished zircons. Altered zircon rims, interpreted to be a result of hydrothermal fluids related to gold mineralization, can be < 3 μm across (Schneider et al., 2012). Therefore, LA-ICP-MS depth profiling may be able to resolve the ages of narrow rims. The Proterozoic ages recorded by zircon in dacite at the Island Gold deposit suggest a Proterozoic alteration event. Further study is needed to determine the cause and identify the specific timing of the alteration event that resulted in the Meso–Neoproterozoic ages recorded by zircon in this sample from the Island Gold deposit.

Some of the rutile in alteration envelopes associated with auriferous veins at the Island Gold deposit is also believed to have formed due to alteration related to gold mineralization. As a result, U-Pb dating of rutile is suggested to determine the age(s) of gold mineralization at the Island Gold deposit.

Differentiating between the gabbro, gabbro/lamprophyre, and silica-poor diorite–monzodiorite

In many cases, it is challenging to distinguish between the gabbro, gabbro/lamprophyre, and silica-poor diorite–monzodiorite at the Island Gold deposit macroscopically. This problem is exacerbated when examining dust-covered walls in the damp, poorly-lit conditions typical of underground mine workings. Key mineralogical, textural, and chemical differences between these lithologies that can be used to help distinguish between them are discussed below.

The silica-poor diorite–monzodiorite is composed of less chlorite when compared to the gabbro and gabbro/lamprophyre. This results in the silica-poor diorite–monzodiorite generally having a lighter colour than either of these two lithologies. The silica-poor diorite–monzodiorite also often has a large proportion of biotite which is not present in the gabbro/lamprophyre and was only observed in the gabbro if it was altered by nearby auriferous quartz veins. Furthermore, the silica-poor diorite–monzodiorite often has a slight pink colouration due to hematite and this is diagnostic when comparing this lithology to the gabbro or gabbro/lamprophyre. Lastly, when these three lithologies are located in the same area, the silica-poor diorite–monzodiorite is typically less deformed than both the gabbro and the gabbro/lamprophyre. When compared to the gabbro, the gabbro/lamprophyre has a larger proportion of carbonate minerals and quartzofeldspathic minerals, but less epidote and chlorite.

Despite the substantial amount of carbonate minerals in the gabbro/lamprophyre, this lithology typically has no reaction or only a weak reaction with HCl. This lithology is also usually non-magnetic. These features can be used to distinguish it from the gabbro and silica-poor diorite–monzodiorite which both often react with HCl and are magnetic. The silica-poor diorite–monzodiorite is typically magnetic and often reacts with dilute HCl. The gabbro may be either magnetic or non-magnetic but consistently reacts with dilute HCl. These basic field tests may be useful in helping differentiate between these lithologies.

The higher concentration of magnesium, chromium, and nickel in the gabbro/lamprophyre when compared to the gabbro and silica-poor diorite–monzodiorite can be used to chemically differentiate the gabbro/lamprophyre from these lithologies. Gabbro/lamprophyre also has lower aluminum than both the gabbro and the silica-poor diorite–monzodiorite. The gabbro/lamprophyre also has comparatively lower titanium and total iron when compared to the gabbro. Furthermore, the

gabbro/lamprophyre has lower concentrations of the elements niobium, yttrium, and zirconium compared to the silica-poor diorite–monzodiorite. These elements are often considered to be relatively immobile (e.g. Winchester and Floyd, 1977; Pearce, 1996). It has been proposed that the silica-poor diorite–monzodiorite may be an altered version of gabbro/lamprophyre. However, the significant chemical differences between the two lithologies, including the different concentrations of immobile elements, suggest that these lithologies have two distinct protoliths.

When compared to the chemistry of the gabbro, the silica-poor diorite–monzodiorite is characterized by high calcium, potassium, and sodium, and these relationships can be used to chemically differentiate these two lithologies. The silica-poor diorite–monzodiorite also has comparatively lower iron, cobalt, and nickel when compared to the gabbro. Furthermore, silica-poor dioritic–monzodioritic samples also have higher concentrations of the elements niobium, thorium, and zirconium than gabbro. These elements are often considered to be immobile elements (e.g. Winchester and Floyd, 1977; Pearce, 1996; Hastie et al., 2007) which indicates that these lithologies have two distinct protoliths as well.

Blue Quartz

Large quartz phenocrysts within the dacitic volcanic rocks and the Webb Lake stock are commonly observed at the Island Gold deposit. Previous studies have attributed the blue colour of quartz to inclusions of titanium-rich minerals causing Rayleigh scattering of light (Seifert et al., 2011). This is likely responsible for the blue-coloured quartz grains commonly observed at the Island Gold deposit because titanium-rich micro-inclusions of ilmenite and rutile were observed within these grains.

Summary of hydrochloric acid and magnetism field test observations for altered samples

The results of dilute hydrochloric acid (HCl) and magnetism tests on altered samples for a number of lithologies at the Island Gold deposit are summarized below. A summary of the results of these field tests on least-altered samples of each lithology is located in Table 19 (Appendix B).

Samples of dacite altered by nearby V_1-V_2 veining are typically non-magnetic but occasionally may be weakly magnetic due to the presence of pyrrhotite in moderately and strongly-altered samples. Primary magnetite occasionally results in weak magnetism in weakly-altered and least-altered samples. Samples altered by V_{GD} veins are all non-magnetic. Dacitic samples altered by V_1-V_2 veins react with dilute hydrochloric acid (HCl). In most cases, strongly and moderately-altered samples have the strongest reaction but occasionally, silicified strongly-altered samples have no reaction or only a weak reaction with HCl. Samples altered by V_{GD} veins also react with HCl. The intensity of the reaction increases with increasing alteration strength. These samples are also non-magnetic. Dacitic samples altered by non-auriferous carbonate-sericite alteration strongly react with HCl. These samples are also magnetic.

Samples of gabbro altered by V_1-V_2 veins react vigorously with HCl and are magnetic. The strength of the reaction remained relatively consistent with varying intensities of alteration. The strength of magnetism decreased with increasing alteration strength. Samples of the Webb Lake stock altered by V_1-V_2 veins react with HCl and the intensity of the reaction increases with increasing alteration strength. Altered samples are non-magnetic. A sample of the gabbro/lamprophyre altered by a proximal V_3 vein is non-magnetic and has no reaction or only a very weak reaction with HCl. A sample of the silica-poor diorite–monzodiorite altered by a proximal V_3 vein is non-magnetic and has a vigorous reaction with HCl.

Table 19. *Summary of some of the results and interpretations from this thesis. Some pertinent information from other studies is also included.*

Lithology/Vein Textures	Lithology/Vein Features of Least-altered samples	Mineralogy of Least-altered Samples	Interpreted Primary Minerals	Quartz Vein-related Alteration	Timing
Dacitic volcanic rocks (T2, V2, I2): Tuffs, hypabbysal intrusives, flows, and pyroclastic breccias	• Tuffs often contain lapilli to bomb-sized fragments. • Porphyritic–equigranular. • Fine–medium grain size. • Non–moderately magnetic. • No–weak reaction with HCl.	• Plagioclase (andesine), quartz, calcite, biotite, chlorite (ripidolite), white mica (muscovite and illite), and epidote. • Accessory minerals (typically < 1 vol%): Actinolite, apatite, chloritoid, grunerite, hematite, hornblende, ilmenite, magnetite, rutile, siderite, titanite, tourmaline, and zircon.	• Plagioclase (andesine), quartz, and biotite. • Accessory minerals (typically < 1 vol%): Apatite, hornblende, ilmenite, magnetite, and zircon.	• **V_{GD} and V_1-V_2 Auriferous Veining:** • Ca-Mg-Fe carbonate minerals, chlorite (ripidolite), quartz, sulphides (pyrite ± pyrrhotite and chalcopyrite), rutile, and white mica (muscovite). • Gains: As, Au, Bi, K_2O, Rb, S, Se, Te, Tl, W. • Losses: Na_2O, Sr.	• Cross-cut/overlain by all other lithologies. Oldest lithology. • U-Pb: 2749 ± 2 to 2728 ± 2.7 Ma (Turek at al., 1982, 1992). • U-Pb: 2735 ± 8 Ma and 2738 ± 9 Ma (this study). • Pre-D1 deformation (Jellicoe, 2019).
Iron formation (IF)	• Banded/layered or massive. • 5 main layer groups: Sulphide-rich layers, iron oxide-rich layers, chert-rich layers, carbonate-rich layers, and chlorite-rich layers. • Fine–coarse grained. • Non–strongly magnetic. • No–strong reaction with HCl.	• Sulphide and iron oxide-rich layers: Hematite, magnetite, and pyrite. • Sulphide and iron oxide-poor layers: Quartz, carbonate minerals, chlorite, plagioclase. • Accessory minerals: Chloritoid, epidote, ilmenite, white mica, and tourmaline.	• Clay minerals, carbonate minerals, hematite, magnetite, plagioclase, pyrite, pyrrhotite, and quartz.	• Not studied	• Thin layers interbedded with dacite are of equivalent age to dacite. • Larger Michipicoten iron formation overlies/post-dates dacite. • Formed after underlying dacite (U-Pb: 2728.8 ± 2.7 Ma; Turek et al., 1988, 1992) but before the Webb Lake stock (U-Pb: 2724 ± 4.3; Jellicoe, 2019). • Pre-D1 deformation (Jellicoe, 2019).
Gabbro (I3G)	• Sills and dykes. • Equigranular. • Medium grain size. • Non–strongly magnetic. • Moderate–strong reaction with HCl.	• Chlorite (ripidolite), quartz, epidote, calcite, actinolite, titanite, plagioclase (oligoclase–andesine), and hornblende. • Accessory minerals: Chloritoid, hematite, ilmenite, magnetite, phengite, pyroxene, rutile, and tourmaline.	• Plagioclase, pyroxene, and hornblende. • Accessory minerals: Ilmenite, magnetite, and quartz.	• **V_1-V_2 Auriferous Veining:** • Biotite, calcite, chlorite (ripidolite), plagioclase (oligoclase), quartz, rutile, sulphides (pyrite ± pyrrhotite and chalcopyrite), ± minor white mica. • Gains: Au, B, Ba, Cs, K_2O, Li, MnO, Pb, Rb, S, Sm, Sr, Te. • Losses: Bi, Ge, Na_2O, P_2O_5, Sb, Tl.	• Cross-cuts dacite and likely cross-cuts iron formations. Post-dates these lithologies. • Formed after dacitic volcanic rocks (Youngest U-Pb age: 2728.8 ± 2.7 Ma; Turek et al., 1988, 1992) but before the Webb Lake stock (U-Pb: 2724 ± 4.3; Jellicoe, 2019). • Likely pre-D1 deformation.

Lithology/Vein Textures	Lithology/Vein Features of Least-altered samples	Mineralogy of Least-altered Samples	Interpreted Primary Minerals	Quartz Vein-related Alteration	Timing
Tonalite–trondhjemite (I1JM: Webb Lake stock)	• Large intrusive body with associated dykes. • Phaneritic, equigranular. • Medium–coarse grain size. • Non-magnetic. • No–weak reaction with HCl.	• Plagioclase (albite–oligoclase), quartz, chlorite (ripidolite), biotite, white mica (phengite ± muscovite), epidote, and calcite. • Accessory minerals: Actinolite, apatite, chloritoid, hematite, hornblende, ilmenite, pyrite, pyroxene, rutile, titanite, tourmaline, and zircon.	• Plagioclase (albite–oligoclase), quartz, and biotite. • Accessory minerals: Apatite, hornblende, ilmenite, pyroxene, and zircon.	• **V_1-V_2 Auriferous Veining:** • Biotite, Ca-Mg-Fe carbonates, chlorite (ripidolite), quartz, rutile, sulphides (pyrite ± pyrrhotite and chalcopyrite), and white mica (muscovite ± phengite). • Gains: Ag, As, Au, B, Bi, C, CO_2, Cu, Fe_2O_3, Ge, K_2O, LOI, Mo, Rb, S, Se, Ta, Te, U, W. • Losses: CaO, Co, Fe_2O_3T, FeO, MnO, Na_2O, Sc, SiO_2, Sm.	• Cross-cuts dacite, iron formations, and gabbro. Post-dates these lithologies. • U-Pb: 2724 ± 4.3 (Jellicoe, 2019). • Syn-D1 deformation (Jellicoe, 2019).
V_{GD} veins: Auriferous quartz-carbonate extensional veins	• Shallowly-dipping. • Semi-opaque, white. • Large, consistent alteration envelopes. • Non-magnetic. • No–weak reaction with HCl.	• Quartz and carbonate minerals. • Common accessory minerals: Actinolite, biotite, chlorite, tourmaline, sulphide minerals, white mica, free gold, and others depending on host lithology.	• N/A	• N/A	• Cross-cuts/alters dacite, iron formations, gabbro, and Webb Lake stock. Post-dates these lithologies. • Prior to or early D2 deformation (Jellicoe, 2019).
V_1-V_2 veins: Auriferous quartz-carbonate shear-related veins	• Steeply-dipping. • White-grey, translucent. • Large, consistent alteration envelopes. • Non-magnetic. • No–weak reaction with HCl.	• Quartz and carbonate minerals. • Common accessory minerals: Actinolite, biotite, chlorite, tourmaline, sulphide minerals, white mica, free gold, and others depending on host lithology.	• N/A	• N/A	• Cross-cuts/alters dacite, iron formations, gabbro, and the Webb Lake stock. V_1-V_2 vein-bearing shears deform V_{GD} veins. Post-dates these lithologies/veins. • Late-D2 deformation (Jellicoe, 2019).
Lamprophyre: Spessartite or Gabbro: Sub-volcanic equivalent to OIB or CFB (I2H)	• Dykes and sills. • Equigranular. • Fine–medium grain size. • Non-magnetic. • No–weak reaction with HCl.	• Quartz, plagioclase (oligoclase–andesine), carbonate minerals, chlorite, and white mica. • Accessory minerals: Actinolite, epidote, hematite, rutile, tourmaline, and zircon.	• Plagioclase, hornblende, pyroxene, and potentially olivine. • Accessory minerals: Zircon.	• **V_3 Non-auriferous Veining:** • White mica (± fuchsite) and carbonates. • Gains: As, Au, B, Ba, Bi, Ce, Cr, Cs, Ga, Ge, K_2O, La, Li, Mo, Rb, Sb, Sr, V, W, Zn. • Losses: Ag, C, CaO, Co, CO_2, Dy, Er, LOI, Lu, MgO, MnO, Na_2O, Ni, Pb, Se, SiO_2, Tb, Tm, Y, Yb.	• Cross-cuts V_1-V_2 veins and all earlier lithologies/veins. Post-dates these lithologies/veins. • Likely late-D2 deformation.

Lithology/Vein Textures	Lithology/Vein Features of Least-altered samples	Mineralogy of Least-altered Samples	Interpreted Primary Minerals	Quartz Vein-related Alteration	Timing
Quartz diorite	• Dyke and xenoliths in intrusion of silica-poor diorite–monzodiorite. • Distinct pink–red colour due to hematite. • Phaneritic, equigranular. • Medium grain size. • Weakly magnetic • Weak reaction with HCl.	• Plagioclase (albite), quartz, carbonate minerals, hematite, and chlorite. • Accessory minerals: Biotite, epidote, magnetite, titanite, tourmaline, white mica, and zircon.	• Plagioclase (albite), and quartz. • Accessory minerals: Biotite, magnetite, and zircon.	• Not studied	• Present as xenoliths within diorite–monzodiorite. Pre-dates this lithology. • Limited extent. Timing uncertain. • Insignificant alteration, metamorphism, and deformation suggests it post-dates the gabbro/lamprophyre. • Likely late or post-D2 deformation.
Silica-poor diorite–monzodiorite (I2M)	• Dykes and sills. • Often has a weak to distinct pink colour. • Phaneritic, equigranular. • Medium grain size. • Weakly–strongly magnetic. • Weak–strong reaction with HCl.	• Plagioclase (oligoclase), carbonate minerals, biotite, chlorite, epidote, magnetite, and orthoclase. • Accessory minerals: Hematite, pyrite, quartz, rutile, titanite, tourmaline, white mica, and zircon.	• Plagioclase (oligoclase), biotite, magnetite, and orthoclase. • Accessory minerals: Pyrite, quartz, white mica, and zircon	• **V_3 Non-auriferous Veining:** • White mica, carbonate minerals, and chlorite • Gains: As, Au, CaO, FeO, Hf, Li, S, Sc, Te, W. • Losses: B, Ba, C, CO_2, Cr, Cs, Cu, Fe_2O_3, Ga, K_2O, LOI, Mo, Na_2O, Ni, Pb, Rb, Sb, Se, Sr, U.	• Contains quartz diorite xenoliths. • Cross-cuts V_1-V_2 veins and earlier lithologies/veins. Post-dates these lithologies and vein types. • Believed to post-date gabbro/lamprophyre. • U-Pb: 2672.2 ± 3.5 Ma (Jellicoe, 2019). • Late or post D2 deformation (Jellicoe, 2019).
V_3 veins: Non-auriferous, quartz-carbonate extensional veins	• Milky-white, opaque. • Typically, short and discontinuous. • No to small envelope. • Inconsistent alteration. • Non-magnetic. • No–weak reaction with HCl.	• Quartz and carbonate minerals. • Varies depending on host lithology.	• N/A	• N/A	• Sporadically present in all lithologies except Diabase. • Cross-cuts V_{GD} and V_1-V_2 veins. • Post-dates diorite–monzodiorite and all prior lithologies/veins. • Syn-D3 deformation (Jellicoe, 2019).

Lithology/Vein Textures	Lithology/Vein Features of Least-altered samples	Mineralogy of Least-altered Samples	Interpreted Primary Minerals	Quartz Vein-related Alteration	Timing
Tourmalinization / V_4 veins	• Semi-linear ribbons (V_4 veins; Jellicoe et al., 2018) or disseminated alteration minerals. • Tourmaline ribbons invade pre-existing structural conduits.	• Tourmaline (± minor quartz/carbonate minerals if present as a distinct vein).	• N/A	• N/A	• Invades V_3 veins and all other pre-existing lithologies/veins. Post-dates these lithologies. • Late or post-D_3 deformation (Jellicoe, 2019).
Diabase–quartz diabase (l3DD)	• Dykes. • Fine–medium grain size. • Aphanitic–phaneritic, equigranular. • Strongly magnetic.	• Plagioclase (andesine–labradorite), clinopyroxene, orthopyroxene, magnetite, actinolite, chlorite, biotite, quartz, hornblende, and epidote. • Accessory minerals: Carbonate minerals and white mica.	• Plagioclase (andesine–labradorite), clinopyroxene, orthopyroxene, magnetite, quartz, and hornblende.	• N/A	• Sharply cross-cuts all lithologies and vein types. • Timing of all diabase dykes uncertain. • Potentially multiple generations. • Mainly Matachewan dyke swarm (2473 +16/-9 Ma; Heaman, 1997). • Post-D_3 deformation (Jellicoe, 2019).

Appendix C

Grab sample information (Underground and surface)

Spatial data: UTM Zone 16U, North American 1983 datum. Elevation is measured in metres above sea level (m ASL). Additional sample information as well as most of the data presented in this appendix are also presented in an open file report (Ciufo et al., 2019).

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T5	Tonalite-Trondhjemite	Weakly-altered Webb Lake Stock, tonalitic-trondhjemitic intrusive rock. Chlorite and carbonate alteration. Altered by nearby V_1-V_2 veins.	688860	5351125	380-400	1						
T6	Tonalite-Trondhjemite	Weakly-altered Webb Lake Stock, tonalitic-trondhjemitic intrusive rock. Chlorite and carbonate alteration. Altered by nearby V_1-V_2 veins.	688860	5351125	380-400	1	1					
T7	Tonalite-Trondhjemite	Weakly-altered Webb Lake Stock, tonalitic-trondhjemitic intrusive rock. Chlorite and carbonate alteration. Altered by nearby V_1-V_2 veins.	689950	5351700	380-400	1						
T8	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock with feldspar and blue quartz phenocrysts.	689950	5351700	380-400	1	1					
T9	Diabase-Quartz Diabase	Diabase-Quartz Diabase dyke.	690700	5352230	380-400	1	1					
T11	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock with feldspar and blue quartz phenocrysts.	690460	5352335	380-400	1	1					
T12	Diabase-Quartz Diabase	Diabase-Quartz Diabase dyke.	690350	5352510	380-400	1	1					
T17	Felsic-intermediate volcanic rock	Moderately-altered felsic-intermediate volcanic rock. <3% pyrite, moderately-strongly foliated, non-magnetic. Chlorite, sericite, pyrite, and carbonate alteration. Altered by nearby V_1-V_2 veins.	690673	5351573	-361	1	1				1	
T19	Mafic intrusive rock	Weakly-altered mafic intrusive rock consisting of mostly chlorite and small carbonate veinlets. Altered by nearby V_1-V_2 veins.	690517	5351529	-361	1	1					

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T20	Felsic-intermediate volcanic rock	Moderately-altered felsic-intermediate volcanic rock. <3% pyrite, moderately-strongly foliated, non-magnetic. Chlorite, sericite, pyrite, and carbonate alteration. Altered by nearby V_1-V_2 veins.	690477	5351533	-361	1	1				1	
T21	Felsic-intermediate volcanic rock	Felsic-intermediate volcanic rock with randomly-oriented chloritoid grains.	690800	5352600	380-400	1	1					
T24	Iron Formation	Sulphide-rich iron formation.	690800	5352600	380-400	1	1			1	1	
T27	Felsic-intermediate volcanic rock	Felsic-intermediate volcanic rock with feldspar and blue quartz phenocrysts, intruded/brecciated by chlorite-rich rock.	692170	5352770	380-400	1	1				1	
T28	Felsic-intermediate volcanic rock	Felsic-intermediate volcanic rock with feldspar and blue quartz phenocrysts, intruded/brecciated by chlorite-rich rock.	692170	5352770	380-400	1						
T29	Felsic-intermediate volcanic rock	Chlorite-rich matrix component of fragmental felsic-intermediate tuff (sample of matrix only).	692275	5352470	380-400	0	1					
T31	Felsic-intermediate volcanic rock	Chloritoid-rich felsic-intermediate volcanic fragment encompased by a more chlorite-rich matrix (sample of clast only).	692275	5352470	380-400	1	1					
T32	Felsic intrusive rock	Altered felsic intrusive rock.	692330	5352330	380-400	1	1					
T36	Felsic-intermediate volcanic rock	Altered felsic-intermediate volcanic rock with feldspar and blue quartz phenocrysts.	694700	5352400	380-400	1						
T37	Iron formation	Sulphide-rich iron formation.	690635	5350620	380-400	1	1			1	1	
T38	Iron formation	Banded iron formation with chert, carbonate, chlorite, and biotite-rich layers.	690635	5350620	380-400	1	1					
T39	Mafic intrusive rock	Mafic intrusive rock with small, sulfide-bearing quartz veinlets.	692170	5352770	380-400	1	1					

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T40	Breccia	Altered and deformed breccia consisting of felsic to intermediate clasts and a magnetic, chlorite-rich matrix.	692170	5352770	380-400	1						
T41	Breccia	Altered and deformed breccia consisting of felsic to intermediate clasts and a magnetic, chlorite-rich matrix.	692170	5352770	380-400	1						
T42	Felsic-intermediate intrusive rock	Altered and strongly-deformed felsic-intermediate intrusive rock.	692170	5352770	380-400	1	1					
T43	Felsic-intermediate intrusive rock	Felsic-Intermediate volcanic rock with feldspar and blue quartz phenocrysts, appears to be intruded/brecciated by chlorite-rich rock.	692170	5352770	380-400	1	1					
T45	Felsic intrusive rock	Felsic intrusive rock.	691650	5352930	380-400	1	1					
T46	Felsic rock	Altered felsic fragment with minor disseminated pyrite content.	692170	5352770	380-400	1						
T47	Mafic intrusive rock	Altered, pyrite-bearing, chlorite-rich intrusive rock with a strong foliation.	692170	5352770	380-400	1						
T48	Felsic intrusive rock	Felsic-intrusive rock.	691750	5351540	380-400	1						
T56	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, some quartz veining present, ~8% pyrite, strongly-foliated, weakly magnetic outside of quartz veins, weak reaction with HCl. Silica, pyrite, sericite, and carbonate alteration. Altered by nearby V_1-V_2 veins.	690813	5351716	-90	1	1				1	
T58	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, ~3% disseminated pyrite, strongly-foliated, non-magnetic, weak reaction with HCl. Sericite, silica, pyrite, carbonate, and chlorite alteration alteration. Altered by nearby V_1-V_2 veins.	690813	5351715	-90	1	1				1	

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T59	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock, carbonate veinlets/flooding, trace pyrite, moderately-foliated, non-magnetic, strong reaction with HCl. Carbonate, chlorite, and minor pyrite alteration. Altered by nearby V_1-V_2 veins.	690814	5351714	-90	1	1					
T66	Diorite-Monzodiorite	Grey with slight pink colour, some hematite content, relatively equigranular and homogeneous, mineral grains <1mm across, ~1% disseminated euhedral pyrite, weak-moderate foliation, moderately-magnetic, weak reaction with HCl.	690576	5351551	-361	1	1					
T70	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, ~13% disseminated and stringers of disseminated fine-grained pyrite, strongly-foliated, non-magnetic, moderate-weak reaction with HCl. Silica, pyrite, sericite, carbonate, and chlorite alteration. Altered by nearby V_1-V_2 veins.	690446	5351535	-361	1						
T71	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock with some V_1-V_2 veining. Pyrite densely concentrated at the contact between quartz veinlets and volcanic rock. Dense stringers and disseminated pyrite ~20%, strongly-foliated, non-magnetic, strong reaction with HCl in carbonate-rich areas of V_1-V_2 veins, no reaction elsewhere. Silica, pyrite, sericite, and carbonate alteration.	690446	5351535	-361	1	1			1	1	
T72	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, visible blue quartz phenocrysts, 10% pyrite, strongly-foliated, non-magnetic, weak reaction with HCl. Silica, pyrite, sericite, and carbonate alteration. Altered by nearby V_1-V_2 veins.	690446	5351535	-361	1	1				1	

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T73	Felsic-intermediate volcanic rock	Moderately-altered felsic-intermediate volcanic rock, ~4% sulfides (2% pyrite, 2% pyrrhotite), strongly-foliated, weakly magnetic due to pyrrhotite, moderate reaction with HCl. Sericite, chlorite, carbonate, and sulphide alteration. Altered by nearby V_1-V_2 veins.	690444	5351534	-361	1	1			2	1	
T76	Felsic-intermediate volcanic rock	Moderately-strongly-altered felsic-intermediate volcanic rock, quartz +/- carbonate flooding/veining, sub-mm across tourmaline seams, ~1% pyrite, strongly-foliated, non-magnetic, strong-moderate reaction with HCl. Sericite, carbonate, chlorite, and pyrite alteration. Altered by nearby V_1-V_2 veins.	690895	5351706	-235	1						
T77	Felsic-intermediate volcanic rock	Moderately-altered felsic-intermediate volcanic rock, ~1% disseminated pyrite, strongly-foliated, non-magnetic, moderate reaction with HCl. Sericite, carbonate, chlorite, and pyrite alteration. Altered by nearby V_1-V_2 veins.	690895	5351706	-235	1						
T78	Felsic-intermediate volcanic rock	Moderately-strongly-altered felsic-intermediate volcanic rock, ~3% disseminated pyrite, strongly-foliated, non-magnetic, strong reaction with HCl. Carbonate, sericite, chlorite, and pyrite alteration. Altered by nearby V_1-V_2 veins.	690895	5351705	-235	1						
T79	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock, blue quartz phenocrysts, sulfide barren, strongly-foliated, non-magnetic, strong reaction with HCl. Chlorite and carbonate alteration. Altered by nearby V_1-V_2 veins.	690895	5351704	-235	1						
T80	Gabbro	Least-altered gabbro, trace disseminated pyrite, non-magnetic, strong reaction with HCl.	690557	5351594	-340	1	1					
T81	Gabbro / Lamprophyre	Ultramafic-mafic intrusive rock, some large 1-8mm across carbonate grains present, sulfide barren, non-magnetic, weak reaction with HCl.	690568	5351589	-340	1	1					

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T82	Gabbro / Lamprophyre and felsic-intermediate volcanic rock	Contact between ultramafic-mafic intrusive rock and felsic-intermediate volcanic rock, linear tourmaline ribbons on contact, carbonate veinlets and pods, non-magnetic, strong reaction with HCl in carbonate veinlets, weak elsewhere.	690568	5351589	-340	1						
T83	Diabase-Quartz Diabase	Diabase dyke, appears undeformed, weak foliation, moderately-magnetic, no reaction with HCl.	690809	5351715	-90	1	1					
T85	Felsic-intermediate volcanic rock	Moderately-altered felsic-intermediate volcanic rock, some V_1-V_2 veinlets, ~4% pyrite, weakly magnetic in some places, weak reaction with HCl. Sericite, silica, carbonate, pyrite, and chlorite alteration.	690394	5351501	-275	1	1				1	
T86	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, some minor V_1-V_2 veinlets, tourmaline ribbons, ~4% pyrite, non-magnetic, strong reaction with HCl. Silica, sericite, carbonate, and pyrite alteration.	690394	5351501	-275	1	1				1	
T87	Gabbro	Weakly-altered gabbro, trace pyrite, moderately-magnetic, moderate reaction with HCl. Chlorite, carbonate, and minor pyrite alteration. Altered by nearby V_1-V_2 veins.	690394	5351500	-275	1	1					
T88	Felsic-intermediate volcanic rock	Moderately-altered felsic-intermediate volcanic rock, trace pyrite, strongly-foliated, layered appearance, strongly-magnetic in more mafic layers, moderately-magnetic elsewhere, moderate reaction with HCl. Carbonate, sericite, chlorite, and pyrite alteration. Altered by nearby V_1-V_2 veins.	690395	5351499	-275	1	1					
T89	Gabbro	Least-altered gabbro, non-magnetic, weakly to moderately-foliated, weak-moderate reaction with HCl.	690569	5351568	-275	1	1					

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T90	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock with V_1-V_2 veining, strongly-foliated, ~12% disseminated and stringer pyrite, non-magnetic, no reaction with HCl. Silica, sericite, and pyrite alteration.	690545	5351544	-275	1	1				1	
T94	Tonalite-Trondhjemite	Likely a moderately-altered sample of the Webb Lake Stock (uncertain) altered by both V_1-V_2 and V_{GD} veins. Prominent pink minerals (either K-spar or hematite), minor quartz veining, blue quartz phenocrysts, weakly-moderately foliated, non-magnetic, strong reaction with HCl, sulfide barren. Chlorite, carbonate, sericite, and silica alteration.	691182	5352156	200	1	1					
T98	Gabbro	Moderately-altered gabbro altered by both V_1-V_2 and V_{GD} veins, chloritic schist with abundant quartz-carbonate veinlets, 1% disseminated pyrite, strongly-foliated, non-magnetic, weak-moderate reaction with HCl outside veinlets, strong reaction within veinlets. Carbonate, chlorite, silica, and pyrite alteration.	691186	5352160	200	1	1				1	
T99	Gabbro	Strongly-altered gabbro altered by both V1-V2 and V_{GD} veins, quartz-carbonate veinlets, 15% disseminated pyrite, strongly-foliated, non-magnetic, strong reaction with HCl. Carbonate, chlorite, silica, and pyrite alteration.	691186	5352160	200	1	1				1	
T100	Auriferous quartz-carbonate vein	V_{GD} quartz-carbonate vein, white, semi-opaque, folded, subhorizontal, small fragments of the gabbroic host-rock are included in the vein, pyrite is concentrated at the margins of the vein or within the gabbroic rock, ~8% pyrite, non-magnetic, weak-moderate reaction with HCl in V_{GD} vein, strong reaction in gabbro adjacent to vein.	691186	5352160	200	1	1			1	1	

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T101	Felsic-intermediate volcanic rock	Strongly-altered gabbro directly below V_{GD} vein and proximal to V_1-V_2 veins. Significant quartz carbonate veining, pyrite concentrated near small quartz carbonate veins, ~5% pyrite, strongly-foliated, non-magnetic, strong reaction with HCl. Chlorite, carbonate, silica, and pyrite alteration.	691186	5352160	200	1	1				1	
T102	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock, trace cubic pyrite, moderately-strongly-foliated, non-magnetic, strong reaction with HCl. Carbonate, chlorite, sericite, and pyrite alteration. Altered by both V_1-V_2 and V_{GD} veins.	691186	5352159	200	1	1					
T104	Auriferous quartz-carbonate vein	V_{GD} quartz-carbonate vein, subhorizontal quartz vein, trace pyrite concentrated near contacts with felsic-intermediate volcanic rock fragments within vein, non-magnetic, no reaction with HCl.	691187	5352176	200	1	1					
T105	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock directly adjacent to a V_{GD} vein, ~4% disseminated pyrite, strongly-foliated, seams of possible tourmaline or chlorite are also present, non-magnetic, strong-moderate reaction with HCl. Sericite, silica, carbonate, pyrite, and chlorite alteration.	691187	5352176	200	1	1				1	
T112	Gabbro	Weakly-moderately-altered gabbro, quartz-carbonate veinlets, trace disseminated fine-grained pyrite, strongly-foliated, non-magnetic, strong reaction with HCl. Chlorite, carbonate, and pyrite alteration. Altered by nearby V_{GD} and V_1-V_2 veining.	691191	5352174	200	1						
T113	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, minor quartz-carbonate veinlets, ~3% pyrite, strongly-foliated, non-magnetic, strong reaction with HCl. Sericite, carbonate, pyrite, and silica alteration. Altered by nearby V_{GD} veining.	691187	5352176	200	1	1				1	

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T114	Felsic-intermediate volcanic rock	Moderately-altered felsic-intermediate volcanic rock, ~2% disseminated fine-grained pyrite, strongly-foliated, non-magnetic, strong reaction with HCl. Carbonate, sericite, chlorite, and pyrite alteration. Altered by nearby V_{GD} veining.	691186	5352176	200	1	1					
T115	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock, some carbonate veinlets, strongly-foliated, non-magnetic, strong reaction with HCl. Carbonate, sericite, silica, and pyrite alteration. Altered by nearby V_{GD} veining.	691186	5352176	200	1	1					
T116	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock, macroscopically visible blue quartz phenocrysts, sulphide barren, moderately-foliated, non-magnetic, weak reaction with HCl.	691214	5352095	200	1	1					
T119	Auriferous quartz-carbonate vein	V_1-V_2 quartz with minor carbonate vein with tourmaline ribbons, visible gold, intrudes through strongly-altered felsic-intermediate volcanic rock. Pyrite is concentrated at the margins of the vein and near fragments of the wall-rock within the vein.	691185	5352178	-360	1						
T127	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, minor quartz-carbonate veinlets, ~3-4% pyrite, strongly-foliated, non-magnetic, moderate reaction with HCl. Sericite, carbonate, pyrite, and silica alteration. Altered by nearby V_1-V_2 veining.	690766	5351588	-385					1		
T128	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, minor quartz-carbonate veinlets, ~3-4% pyrite, strongly-foliated, non-magnetic, moderate reaction with HCl. Sericite, carbonate, pyrite, and silica alteration. Altered by nearby V_1-V_2 veining.	690764	5351592	-385			1				
T129	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock with quartz and feldspar phenocrysts, moderately-foliated, non-magnetic, weak reaction with HCl.	690565	5351588	-385			1				

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T134	Nepheline syenite	Herman Lake Intrusive Complex nepheline syenite, medium-coarse grained, relatively unaltered.	687326	5354240	388	1	1					
T136	Nepheline syenite	Herman Lake Intrusive Complex nepheline syenite, coarse-grained, pink potassium feldspar or potentially hematite-staining visible.	688580	5354645	423	1						
T138	Granodiorite	Medium-grained granodiorite from the Maskinonge Lake Intrusion.	688313	5356171	466	1						
T165	Intermediate intrusive rock	Intermediate intrusive rock located in a small shear zone intruding through mafic volcanic rocks.	688630	5353737	406	1	1					
T168	Gabbro	Medium-coarse grained gabbro intruding through mafic volcanic rocks.	688939	5353169	437	1						
T170	Basalt	Fine-grained mafic volcanic rock.	689378	5352918	427	1						
T173	Diabase-Quartz Diabase	Medium-grained, mafic intrusive rock intruding in felsic-intermediate volcanic rocks.	692330	5351391	404	1						
T178	Auriferous quartz-carbonate vein	Gold-bearing V_1-V_2 vein with fuchsite.	690686	5351577	-396	2						
T182	Gabbro	Least-altered gabbro, medium-grained, intruding through felsic-intermediate volcanic rock.	697448	5351475	417	1	1					
T183	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock, some chlorite and carbonate alteration.	696682	5351495	410	1	1					
T189	Granodiorite	Medium-grained Maskinonge Lake granodiorite.	688198	5356123	479	1	1					
T197	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, near both a large diabase intrusion and V_1-V_2 veining. Sericite, carbonate, silica, and pyrite alteration.	690802	5351600	-392	1						
T199	Iron Formation	Sulphide-rich iron formation.	685546	5349403	402					1		
T200	Gabbro	Least-altered gabbro, medium-grained, intruding through felsic-intermediate volcanic rock.	692869	5350600	387	1	1					

ID	Lithology	Brief Sample Description	Easting	Northing	Elevation (m ASL)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T208	Porphyritic felsic intrusive rock	Porphyritic felsic intrusive with large feldspar phenocrysts. Potentially a sample of the Webb Lake Stock but uncertain.	692321	5352445	414	1						
T213	Gabbro / Lamprophyre	Hydrothermally-altered mafic-ultramafic intrusive rock altered by a V_3 non-auriferous quartz vein.	690666	5351577	-394.557	1	1					
T215	Quartz Diorite	Xenoliths of a coarse-grained, hematite-rich, felsic intrusive rock within a larger dioritic-monzodioritic intrusion. Weakly-magnetic, weak reaction with HCl.	690912	5351666	-231.065	1	1					
T216	Diorite-Monzodiorite	Diorite-monzodiorite hosting the sample described in T215, grey colour, minor hematite content, strongly-magnetic, moderate reaction with HCl.	690912	5351666	-231.065	1	1					
T228	Diorite-Monzodiorite	Diorite-monzodiorite with significant hematite content, mainly composed of biotite/chlorite, plagioclase, and carbonate minerals. Moderately-strongly-foliated, strongly-magnetic, weak reaction with HCl.	690641	5351572	-394.67	1	1					
T229	Non-auriferous quartz-carbonate vein and Gabbro / Lamprophyre	V_3 non-auriferous quartz vein in contact with an altered mafic-ultramafic intrusive rock. The intrusive rock exhibits fuchsite, sericite, and carbonate alteration at the contact with the vein which decreases in intensity moving away from the vein.	690677	5351574	-393.609	1						
T243	Quartz Diorite	Coarse-grained, felsic intrusive rock with substantial hematite content, weakly-magnetic, weak reaction with HCl.	690907	5351672	-209.775	1						
T244	Diorite-Monzodiorite	Deformed diorite-monzodiorite, taken adjacent to sample 245, some hematite content, moderately-foliated, non-magnetic, moderate reaction with HCl.	690876	5351624	-644	1						
T245	Diorite-Monzodiorite	Diorite-monzodiorite altered by V_3 non-auriferous quartz veins. This sample is located adjacent to T244. Abundant carbonate veinlets, strongly-foliated, non-magnetic, strong reaction with HCl. Chlorite, carbonate, and minor sericite alteration.	690876	5351624	-644	1	1					

Appendix D

Drill core sample information

Additional sample information as well as most of the data presented in this appendix are also presented in an open file report (Ciufo et al., 2019). Additional spatial data pertaining to drill holes in Ciufo et al. (2019) is from Alamos Gold Inc. and Richmont Mines Inc.

ID	Lithology	Brief Sample Description	Hole ID	From (m)	To (m)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T13	Felsic-intermediate volcanic rock	Felsic-intermediate volcanic rock with lapilli sized volcanic fragments of similar composition.	740-477-09	79.5	80.1	1	1					
T14	Gabbro	Least-altered gabbro, carbonate veinlets, chlorite alteration, non-magnetic, strong reaction with HCl.	740-477-09	69	69.5	1	1					
T15	Gabbro / Lamprophyre	Mafic-ultramafic intrusive rock, non-magnetic, no reaction with HCl.	740-477-09	128.8	129.1	1	1					
T16	Diorite-Monzodiorite	Diorite-Monzodiorite, grey-pink colour, some hematite content, moderately-magnetic, moderate reaction with HCl.	740-477-09	130.5	130.9	1	1			1	1	
T50	Mafic-ultramafic intrusive rock	Altered mafic-ultramafic intrusive rock, exact lithology uncertain, ~1% disseminated pyrite, non-magnetic, strong-moderate reaction with HCl. Strong chlorite and carbonate alteration.	740-471-18	166	166.8	1	1					
T62	Gabbro	Gabbro, sulfide barren, strongly-foliated, non-magnetic, strong reaction with HCl. Chlorite and carbonate alteration.	740-477-30	189.5	189.8	1						
T63	Gabbro / Lamprophyre	Weakly deformed ultramafic-mafic intrusive rock, sulfide barren, grain sizes <1mm, non-magnetic, very weak reaction with HCl.	740-477-30	189.8	190.4	1	1					
T65	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock with ~5% feldspathic and blue quartz phenocrysts, small carbonate veinlets, sulfide barren, some hematite alteration around carbonate veinlets, moderately-magnetic due to trace magnetite, no reaction with HCl outside of small carbonate veinlets.	740-477-30	190.2	192.15	1	1					
T106	Gabbro	Gabbro with ~50% randomly oriented chloritoid grains, trace pyrrhotite and pyrite, weakly-foliated, non-magnetic, strong reaction with HCl.	740-477-39	540	540.8	1	1					

ID	Lithology	Brief Sample Description	Hole ID	From (m)	To (m)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T107	Felsic-intermediate volcanic rock	Felsic-intermediate volcanic rock with lapilli of similar composition, sulphide barren, contains randomly-oriented chloritoid grains, aphanitic groundmass, non-magnetic.	740-477-39	548.2	548.4	1						
T108	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock (sub-volcanic hypabyssal intrusive rock), relatively homogenous and equigranular, weakly-altered, sub-phaneritic (grains 1mm or less across), trace very fine-grained disseminated pyrite, non-magnetic, no reaction with HCl.	740-477-16	130.6	131.4	1						
T109	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock, porphyritic with quartz and plagioclase phenocrysts and an aphanitic groundmass, minor millimetre wide quartz carbonate veinlets with trace tourmaline concentrated within, weak to moderate foliation, non-magnetic outside of veinlets/fracture fill, ~1% disseminated pyrrhotite or magnetite grains outside of veinlets, weak-moderate reaction with HCl, strong reaction in veinlets. Altered by nearby V_1-V_2 veins.	740-477-16	127.8	128.8	1						
T110	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock (sub-volcanic hypabyssal intrusive rock), relatively equigranular, ~1% pyrite, non-magnetic, minor barren smoky quartz veins in some samples, moderate reaction with HCl. Altered by nearby V_1-V_2 veins.	740-471-35	252.8	253.5	1						
T117	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock (sub-volcanic hypabyssal intrusive rock), ~1% pyrite, appears relatively homogeneous and equigranular, grain size is less than 2mm across, weak-moderate foliation, non-magnetic, no reaction with HCl. Altered by nearby V_1-V_2 veins.	740-465-02	13.3	14.6	1	1					

ID	Lithology	Brief Sample Description	Hole ID	From (m)	To (m)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T118	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock, quartz and feldspar phenocrysts (<3 mm across), ~1% pyrite, weakly-moderately-foliated, non-magnetic, weak reaction with HCl. Altered by nearby V_1-V_2 veins.	740-465-02	15.5	16.2	1	1					
T125	Mafic-ultramafic intrusive rock	Mafic-ultramafic intrusive rock, lithology uncertain.	740-465-44	77	79.9	1						
T126	Mafic-ultramafic intrusive rock	Mafic-ultramafic intrusive rock, lithology uncertain, Altered and deformed version of T125, chlorite and carbonate alteration, strongly-foliated.	740-465-44	79.9	80.3	1						
T139	Gabbro	Weakly-altered gabbro, trace disseminated sulfides, ~1% disseminated magnetite, <2mm wide carbonate veinlets/seams, weakly-foliated, strongly-magnetic, moderate-strong reaction with HCl. Chlorite, carbonate, and pyrite alteration. Altered by nearby V_1-V_2 veins.	740-465-46	168.3	169	1	1					1
T140	Gabbro	Moderately-altered gabbro, ~1-2% disseminated pyrite, <2mm scale carbonate veinlets/seams, moderately-foliated, strongly-magnetic, weak reaction with HCl. Chlorite, carbonate, biotite, and pyrite alteration. Altered by nearby V_1-V_2 veins.	740-465-46	174.4	175	1	1					
T141	Gabbro	Moderately-altered gabbro, 1-2mm thick carbonate veinlets, ~2-3% disseminated pyrite, strongly-foliated, moderately-magnetic, strong reaction with HCl. Chlorite, carbonate, biotite, pyrite, and silica alteration. Altered by nearby V_1-V_2 veins.	740-465-46	175.5	176.2	1	1					1

ID	Lithology	Brief Sample Description	Hole ID	From (m)	To (m)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T142	Gabbro	Strongly-altered gabbro, ~5-7% disseminated pyrite and pyrrhotite, 1 mm to 1 cm across quartz-carbonate veinlets, strongly-foliated, weakly-magnetic, strong reaction with HCl. Carbonate, biotite, silica, pyrite, and chlorite alteration. Altered by nearby V_1-V_2 veins.	740-465-46	176.2	177	1	1			1		
T154	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock, quartz and feldspar phenocrysts, some lapilli-sized fragments of similar composition, moderately-foliated, non-magnetic, moderate reaction with HCl.	GD-620-01	712.8	713.5	1	1					1
T155	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock, quartz and feldspar phenocrysts, some small carbonate veinlets with orange straining - perhaps ankerite or hematite, ~1% pyrite, moderately-foliated, non-magnetic, strong reaction with HCl. Chlorite, carbonate, pyrite, and minor sericite alteration. Altered by nearby V_1-V_2 veins.	GD-620-01	723.2	724.3	1						
T156	Felsic-intermediate volcanic rock	Moderately-altered felsic-intermediate volcanic rock, quartz and feldspar phenocrysts, ~1-3% pyrite and pyrrhotite, some disseminated magnetite, some hematite alteration, strongly-foliated, moderately-magnetic, moderate reaction with HCl. Carbonate, sericite, chlorite, and pyrite alteration. Altered by nearby V_1-V_2 veins.	GD-620-01	727.7	728.5	1	1					
T157	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, ~3-5% pyrite, strongly-foliated, non-magnetic, strong reaction to HCl. Sericite, carbonate, pyrite, chlorite, and silica alteration. Altered by nearby V_1-V_2 veins.	GD-620-01	728.5	728.9	1	1					1

ID	Lithology	Brief Sample Description	Hole ID	From (m)	To (m)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T158	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock with quartz veining/flooding, ~5-7% pyrite, strongly-foliated, non-magnetic, weak-moderate reaction with HCl. Sericite, silica, pyrite, and carbonate alteration. Altered by nearby V_1-V_2 veins.	GD-620-01	728.9	729.7	1	1					
T159	Auriferous quartz-carbonate vein	V_1-V_2 smoky quartz-carbonate vein with visible gold flecks, contains some actinolite, chlorite, sericite, and pyrite, some tourmaline seams/ribbons, non-magnetic, no reaction with HCl. Altered by nearby V_1-V_2 veins.	MH3-7	1400.2	1401.4	1	1					
T161	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, ~5% disseminated pyrite, strongly-foliated, non-magnetic, moderate reaction with HCl. Sericite, carbonate, pyrite, and chlorite alteration. Altered by nearby V_1-V_2 veins.	MH3-7	1406.1	1407.3	1						
T162	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, ~3% disseminated pyrite, strongly-foliated, non-magnetic, no reaction with HCl except in small carbonate seams. Sericite, pyrite, carbonate, and silica alteration. Altered by nearby V_1-V_2 veins.	MH3-7	1409.3	1410.4	1	1					
T163	Felsic-intermediate volcanic rock	Weakly-moderately-altered felsic-intermediate volcanic rock, small discontinuous carbonate veinlets, ~1-2% disseminated pyrite, moderately-foliated, non-magnetic, strong reaction with HCl. Altered by nearby V_1-V_2 veins.	MH3-7	1412.4	1413.6	1						
T164	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock with lapilli of similar composition, a few small carbonate veinlets, weakly-foliated, strongly-magnetic, no reaction with HCl except in the carbonate seams.	MH3-7	1418.5	1419.7	1	1					

ID	Lithology	Brief Sample Description	Hole ID	From (m)	To (m)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T184	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock with quartz and feldspar phenocrysts, minor carbonate veinlets, trace pyrite, moderately-foliated, non-magnetic, weak reaction with HCl. Chlorite, carbonate, weak pyrite, and weak sericite alteration. Altered by nearby V_1-V_2 veins.	PR-UG-144	69.4	70	1	1		1			
T185	Felsic-intermediate volcanic rock	Weakly-altered felsic-intermediate volcanic rock with quartz and feldspar phenocrysts, minor carbonate veinlets, trace pyrite, moderately-foliated, non-magnetic, no reaction with HCl. Chlorite, minor pyrite, and minor sericite alteration. Altered by nearby V_1-V_2 veins.	PR-UG-144	72	72.6	1						
T186	Felsic-intermediate volcanic rock	Moderately-altered felsic-intermediate volcanic rock with quartz and feldspar phenocrysts, ~1-2% pyrite in stringers/bands and disseminated, strongly-foliated, weakly-magnetic, moderate-strong reaction with HCl. Carbonate, sericite, chlorite, and pyrite alteration. Altered by nearby V_1-V_2 veins.	PR-UG-144	78.2	79	1	1		2			
T187	Auriferous quartz-carbonate vein	V_1-V_2 quartz-carbonate vein with visible gold flecks/droplets, lots of sericite clots in the quartz vein, pyrite stringers and disseminated cubes associated with the sericite-rich areas, non-magnetic, no reaction with HCl.	PR-UG-144	81.1	82.2	1	1					
T188	Felsic-intermediate volcanic rock	Strongly-altered felsic-intermediate volcanic rock, clusters and stringers of cubic pyrite (~3-5%), strongly-foliated, non-magnetic, weak reaction with HCl. Sericite, pyrite, silica, and carbonate alteration. Altered by nearby V_1-V_2 veins.	PR-UG-144	82.2	82.8	1	1		1			

ID	Lithology	Brief Sample Description	Hole ID	From (m)	To (m)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T192	Tonalite-trondhjemite	Least-altered Webb Lake Stock, tonalitic-trondhjemitic intrusive rock, some small <1 mm thick carbonate veinlets, trace sulfides, weakly-foliated, non-magnetic, no reaction with HCl outside of carbonate veinlets.	SH-4	430	431.5	1	1					1
T193	Tonalite-trondhjemite	Weakly-altered Webb Lake Stock, tonalitic-trondhjemitic intrusive rock, some <1 mm scale carbonate seams, ~1% pyrite, weakly-foliated, non-magnetic, weak reaction with HCl, non-magnetic. Chlorite, carbonate, biotite, sericite, and pyrite alteration. Altered by nearby V_1-V_2 veins.	SH-4	444.5	445.3	1	1					
T194	Tonalite-trondhjemite	Moderately-altered Webb Lake Stock, tonalitic-trondhjemitic intrusive rock, some small <1 mm across carbonate veinlets, ~2-4% disseminated pyrite, moderately-foliated, non-magnetic, moderate reaction with HCl. Chlorite, sericite, biotite, carbonate, and pyrite alteration. Altered by nearby V_1-V_2 veins.	SH-4	445.3	445.9	1	1					
T195	Tonalite-trondhjemite	Strongly-altered Webb Lake Stock, tonalitic-trondhjemitic intrusive rock, some <1 mm across carbonate veinlets, ~5-7% disseminated pyrite and chalcopyrite, moderately-strongly-foliated, non-magnetic, weak-moderate reaction with HCl. Sericite, silica, sulphide, and carbonate alteration. Altered by nearby V_1-V_2 veins.	SH-4	446	446.9	1	1			2		1
T196	Auriferous quartz-carbonate vein	Smokey V_1-V_2 auriferous quartz-carbonate vein, visible gold droplets/flecks, sericite seams and clots, ~1-2% pyrite and chalcopyrite, non-magnetic, some <1 mm across carbonate seams, no reaction with acid outside of these carbonate seams.	SH-4	446.9	447.4	1	1					

ID	Lithology	Brief Sample Description	Hole ID	From (m)	To (m)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T218	Felsic-intermediate volcanic rock	Intensely-altered felsic-intermediate volcanic rock with quartz and feldspar phenocrysts, abundant tourmaline seams, lacking quartz veinlets, no quartz veining nearby, some small <2 mm across carbonate veinlets, ~1-2% disseminated magnetite, sulphide barren, minerals are stretched and deformed, strongly-foliated, strongly-magnetic, strong reaction with HCl. Sericite and carbonate alteration.	GD-465-02	48.1	49.5	1	1					
T219	Felsic-intermediate volcanic rock	Weakly-moderately-altered felsic-intermediate volcanic rock with quartz and feldspar phenocrysts, abundant tourmaline seams, minor V_3 non-auriferous quartz-carbonate veining, ~1-2% disseminated magnetite, trace pyrite, moderately-foliated, strongly-magnetic, moderate reaction to HCl. Sericite and carbonate alteration.	GD-465-02	46.6	47.4	1						
T220	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock with quartz and feldspar phenocrysts, minor lapilli of similar composition are also present, trace cubic pyrite, ~1-2% disseminated magnetite, a few tourmaline seams/ribbons, lack of deformation, moderate-strong magnetism, no reaction with HCl.	GD-465-02	42.2	43.3	1						
T226	Gabbro	Gabbro, magnetite inclusions in garnet with chloritoid.	MH9-2	1272.5	1272.6	1						
T233	Felsic-intermediate volcanic rock	Felsic-intermediate volcanic rock with hematite alteration and quartz and feldspar phenocrysts	LC-415-04	253.1	253.2	1						
T237	Felsic intrusive rock	Felsic intrusive rock, protolith uncertain.	MH9-2	1562.3	1562.4	1						
T238	Mafic intrusive rock	Mafic xenolith or mafic intrusive rock intruding through felsic intrusive rock (T237). Protolith uncertain.	MH9-2	1562.4	1562.5	1						

ID	Lithology	Brief Sample Description	Hole ID	From (m)	To (m)	Thin Section	Geochemistry	Geochronology	SEM-MLA	^{32}S ^{33}S ^{34}S ^{36}S	^{32}S ^{34}S	Microprobe
T239	Gabbro / Lamprophyre	Mafic-ultramafic intrusive rock, weakly-foliated, medium-coarse-grained, non-magnetic, no reaction with HCl.	700-496-10	9.4	10	1	1					
T240	Gabbro / Lamprophyre	Mafic-ultramafic intrusive rock, medium-grained, non-magnetic, no reaction with HCl.	MH4	261	261.8	1	1					
T241	Felsic-intermediate volcanic rock	Least-altered felsic-intermediate volcanic rock with feldspar and quartz phenocrysts and an aphanitic groundmass.	620-517-24	22.7	23.6	1	1		1			
T242	Diorite-Monzodiorite	Diorite-Monzodiorite, weakly-moderately foliated, moderately-strongly-magnetic, strong reaction with HCl.	620-517-24	61	62	1	1					

Appendix E

Point-counting results

All values are in area percent. Methods are described in Section 3.3.

Appendix H

Electron microprobe data and mineral formulae

Mineral chemical composition data in mass percent (determined via electron microprobe) is from Western University's Earth and Planetary Materials Analysis Lab. Other results in this appendix including mineral formulae and mineral endmember proportions are calculated based on this data. Not detected is abbreviated "nd". Methodology for electron microprobe analyses and other calculations pertaining to data in this appendix are summarized in Sections 3.6 and 4.3.

Appendix I

Electron microprobe configurations and standards

Microprobe configurations and standards used during microprobe analysis for this thesis were provided by Marc Beauchamp at Western University's Earth and Planetary Materials Analysis Lab. Methodology for electron microprobe analysis is summarized in Section 3.6.

Appendix N

Whole-rock geochemistry data including NRCan-provided reference materials

Whole-rock geochemistry data from Activation Laboratories Ltd. Methods are outlined in Section 3.2. These results are from an open file report (Ciufo et al., 2019) with the exception of results pertaining to STPL standards which are also reported in this Appendix.

Appendix O

Whole-rock geochemistry QA/QC data (Lab-provided reference materials, duplicates, and method blanks)

Whole-rock geochemistry QA/QC from Activation Laboratories Ltd. Methods are summarized in Section 3.2. These results are from an open file report (Ciufo et al., 2019).

Appendix P

Whole-rock geochemistry QA/QC analysis of duplicates and lab-provided reference materials

The units for values in the "DL" (detection limit) and "LOQ" (limit of quantification; 3 times DL) columns are indicated in the "Reported Units" column for each row. Std=Standard, RD=Relative difference, CV=Coefficient of variation. Methods are discussed in Section 3.2 and 3.2.1.2.

Appendix Q

Whole-rock geochemistry QA/QC analysis of lab-provided method blanks

The units for values in the DL (detection limit) column are indicated in the "Reported Units" column for each row. Values in the "< DL", "DL to 3x DL (inclusive)", and "> 3x DL" columns are the number of method blanks that fall within the ranges specified. Methods are outlined in Section 3.2 and 3.2.1.2.

Appendix R

Whole-rock geochemistry QA/QC analysis of NRCan-provided reference materials

Historical standard data was provided by Natural Resources Canada (NRCan, personal communication, 2018). The units for values in "DL", "Avg", and "Std Dev" columns are specified in the "Reported Units" column for each row. DL=detection limit, Avg=Average, Std Dev=Standard deviation, RD=Relative difference, RSD=Relative standard deviation. Methods are discussed in Section 3.2 and 3.2.1.1.

Appendix S

Isocon results summary

Results of mass balance calculations based off of the analysis of Isocon diagrams for altered/less-altered pairs are displayed in this appendix. Methods are discussed in Sections 3.2.2 and 3.2.4. Elements selected as immobile are used to determine the slope of the Isocon and are deemed neither enriched nor depleted (referred to as "Immobile" in the tables below). The cause of the alteration (e.g. V_{GD} veins) and lithology (e.g. dacite) is indicated for each altered/less-altered pair. Descriptive terms for the approximate location within the deposit where dacitic altered/less-altered pairs affected by auriferous quartz veining were taken from are included. The locations of each of the alteration envelopes described using these terms are shown in Figure 19. LOI=Loss on ignition, Fe_2O_3T=Total Iron.
